Reduction of  $[\text{Mo}_3\text{E}_4\text{Cl}_4(\text{PEt}_3)_n]$  ( $\text{E} = \text{S}, \text{Se}; n = 3, 4$ ) afforded the molecular clusters  $[\text{Mo}_6\text{E}_8(\text{PEt}_3)_6]$  in which E bridges the triangular faces of the octahedral  $\text{Mo}_6$  core, the metal–metal distances being 2.66–2.67 Å (S) and 2.70–2.71 Å ( $\text{E} = \text{Se}$ ). Related pyridine, pyrrolidine, and piperidine complexes have been described.  $[\text{Mo}_6\text{E}_8(\text{PEt}_3)_6]$  is electroactive, undergoing a single one-electron oxidation and two one-electron reduction steps. Sodium amalgam reduction of the clusters afforded  $[\text{Mo}_6\text{E}_8(\text{PEt}_3)]^-$ , the octahedral structure becoming slightly distorted, and the Mo–Mo distances slightly longer than in the neutral precursor. Reaction of  $[\text{Mo}_6\text{S}_8(\text{PEt}_3)_6]$  with  $\text{NO}^+$  afforded paramagnetic  $[\text{Mo}_6\text{S}_8(\text{NO})(\text{PEt}_3)_5]$ , which has a distorted octahedral metal core, the Mo–Mo bonds involving the Mo atom bound to NO ( $\text{Mo–N–O } 175^\circ$ ) being much longer than the others (2.63 Å). A second product obtained from this reaction,  $[\text{Mo}_{12}\text{S}_{16}(\text{PEt}_3)_{10}]$  consists of two octahedral  $\{\text{Mo}_6\text{S}_8\}$  cores connected to each other by two  $\text{Mo–}\mu_4\text{-S}$  bonds, which is similar to the bridging mode found in solid-state Chevrel phases. This dodecanuclear cluster, and its selenium analog  $[\text{Mo}_{12}\text{Se}_{16}(\text{PEt}_3)_{10}]$ , could also be made by abstraction of  $\text{PEt}_3$  by  $\text{S}_8$  (giving  $\text{SPEt}_3$ ) from  $[\text{Mo}_6\text{E}_8(\text{PEt}_3)_6]$ .

Reaction of the Chevrel phase  $[\text{Mo}_6\text{Se}_8]$  with KCN at  $650^\circ\text{C}$  gave the water-soluble paramagnetic  $[\text{Mo}_6\text{Se}_8(\text{CN})_6]^{7-}$  which could be oxidized in air to the hexa-anionic species. This reaction also afforded insoluble paramagnetic  $[\text{Mo}_6\text{Se}_8(\text{CN})_5]^{6-}$ , whose structure shows that the Mo atoms in the basal plane of each  $\{\text{Mo}_6\text{Se}_8\}$  cluster are bound to four terminal  $\text{CN}^-$  ligands, with the

clusters being linked by CN groups into linear chains, represented as  $\{\text{Mo}_6\text{Se}_8(\mu\text{-CN})\}^{6-}$ . This species exhibits normal Curie–Weiss behavior over the temperature range 1.8–400 K, with  $\mu = 1.99 \text{ BM}$ .

Other octahedral clusters were encountered in  $[\text{Mo}_6\{\text{Se}_2\text{Cl}_6\}\text{Cl}_3]^{3-}$  and  $[\text{Mo}_6(\text{TeCl}_7)\text{Cl}_6]^{3-}$ .

### 7.3.7 $\text{Mo}_6\text{E}_8^{6+}$ Clusters with Raft-like Structures

Reaction of  $[\text{Mo}_3\text{E}_4\text{Cl}_4\text{L}_5]$  ( $\text{E} = \text{S}, \text{Se}; \text{L} = \text{PEt}_3$  and/or THF) with Mg in THF and  $-20^\circ\text{C}$  gave  $[\text{Mo}_6\text{E}_8\text{Cl}_6(\text{PEt}_3)_6]$ , (**71**). This species contains seven Mo–Mo single bonds and the structure was described as formed by two reduced  $\{\text{Mo}_3\text{E}_4\}^{3+}$  triangular clusters held together via a Mo–Mo bond ( $\text{E} = \text{S}, 3.00 \text{ Å}; \text{E} = \text{Se}, 3.06 \text{ Å}$ ). A similar structure was encountered in  $[\text{Mo}_6\text{S}_{10}(\text{SH})_2(\text{PEt}_3)_6]$ , prepared by reaction of  $[\text{NH}_4]_2[\text{Mo}_3\text{S}_{13}]$  with  $\text{PEt}_3$  in THF. In this cluster a Mo–Mo bond again links the two  $\{\text{Mo}_3\text{S}_4\}$  triangles (2.95 Å).

## 1 INTRODUCTION

The group 6 elements molybdenum (Z 42) and tungsten (Z 74) are the only second and third row transition metals (*see Transition Metals*) essential to all forms of life on Earth (*see also Tungsten Proteins and Nutritional Aspects of Metals & Trace Elements*). Molybdenum is found at the active sites (*see Active Site*) of nitrogenase (*see Nitrogenase: Metal Cluster Models and Nitrogenase Catalysis & Assembly*) and all of the more than 50 known Mo-MPT enzymes (*see Enzyme*).<sup>1–7</sup> The Mo-MPT enzymes feature active sites composed of a single (mononuclear) Mo atom coordinated by one or two MPT-based ligands (*see Ligand*) (MPT = 'molybdopterin' or Metal-binding Pterin ene-1,2-diThiolate); tungsten is also associated with MPT-based ligands in all its known biological manifestations (*see Tungsten Proteins*). The Mo-MPT enzymes are important in the metabolism (*see Metabolism*) of small molecules and anions containing nitrogen, sulfur, carbon, selenium, arsenic, and chlorine, and in the global biogeochemical cycles of these elements. The attributes of selected enzymes are summarized in Table 1; details can be found in Sections 4–6.

There have been tremendous developments in this area since the publication of EIC-I.<sup>1</sup> Advances include: (1) the

classification of the enzymes into three families based on sequence and structural comparisons, (2) confirmation of the presence of mononuclear Mo active sites, (3) establishment of the binding mode, redox state, and structural attributes of MPT-based ligands, (4) determination of the composition and structures of the active sites and the emergence of clear targets for model studies, (5) delineation of electron-transfer pathways and reaction mechanisms, and (6) the identification of the genes and proteins involved in MPT biosynthesis and Mo transport, homeostasis (*see Homeostasis*), and regulation.<sup>2–7</sup> Advances in Mo bioinorganic chemistry, particularly the development of OAT/CEPT models and dithiolene (*see Dithiolenes*) synthetic analogues, have accompanied developments on the biological front.<sup>7</sup> Progress in both spheres, viz. enzymatic and synthetic, has depended largely on the continual refinement and application of structural and spectroscopic methods, particularly X-ray crystallography (*see X-ray Crystallography*),<sup>8–11</sup> X-ray absorption spectroscopy (*see X-ray Absorption Spectroscopy*) (especially Extended X-ray Absorption Fine Structure (EXAFS) analysis, *see Extended X-ray Absorption Fine Structure*),<sup>12,13</sup> paramagnetic resonance techniques (Electron Paramagnetic Resonance (EPR), *see Electron Paramagnetic Resonance*; Electron Nuclear Double Resonance (ENDOR), *see Electron Nuclear Double Resonance Spectroscopy*; and Electron Spin Echo Envelope Modulation (ESEEM), *see Electron Spin Echo Envelope Modulation Spectroscopy*),<sup>13–16</sup> resonance Raman spectroscopy (*see Resonance Raman Spectroscopy*),<sup>7,13</sup> Magnetic Circular Dichroism spectroscopy (MCD) (*see Magnetic Circular Dichroism*),<sup>7,13</sup> and advanced electrochemical methods.<sup>17,18</sup>

This account focuses on the Mo bioinorganic chemistry (*see Bioinorganic Chemistry*) of the Mo-MPT enzymes and selected synthetic analogues. It is divided into two main parts. Part 1 (Sections 2–6) provides an overview of the enzyme systems, their distribution, roles, and essential chemistry, as well as a discussion of consensus structures and likely mechanisms. The genes and proteins involved in Mo trafficking and Mo-cofactor biosynthesis are also briefly described. Part 2 (Sections 7–11) summarizes important developments in the production of synthetic analogues, with a focus on new dithiolene, scorpionate (including trispyrazolylborate (*see Tris(pyrazolyl)borates*)) and other complexes sharing the structural, spectroscopic, or chemical attributes of the enzymes.

Current knowledge permits a more definitive description of the enzymes than was possible in EIC-I;<sup>1</sup> however, the fundamental chemistry described therein provides valuable context and valid background for the present account. Since 1994, many reviews of the Mo-MPT enzymes and/or their Mo chemistry have appeared; the major reviews of Hille,<sup>2,3</sup> Pilato and Stiefel,<sup>4</sup> and more recently, Tunney, McMaster, and Garner,<sup>5</sup> deserve special mention (focused reviews are cited in the text). Molybdenum-MPT enzymes and metallodithiolenes were the subjects of recent thematic issues of *Metal Ions in*

**Table 1** Properties of selected Mo-MPT enzymes

| Enzyme                                      | Source                    | Subunits,<br>mass (kDa) <sup>a</sup>       | Composition <sup>b</sup>                                                                                     | Conversion catalyzed                                                                        | PDB code <sup>c</sup> |

## 2 DISTRIBUTION, CLASSIFICATION, AND GENERAL CHEMISTRY OF Mo-MPT ENZYMES

### 2.1 General Distribution

The enzymes are widely distributed in microorganisms, plants, and animals.<sup>1-6</sup> Three Mo-MPT enzymes have been found in mammals: (1) xanthine dehydrogenase (*see Dehydrogenase*) has many, varied roles in purine catabolism, drug metabolism, and oxidative stress response, (2) aldehyde oxidase is important in drug metabolism and the synthesis of retinoic acid from retinal, and (3) sulfite oxidase plays a crucial role in the detoxification of sulfite produced in the degradation of cysteine and methionine. Genetic Mo-MPT deficiency in

humans results in serious neurological disorders and infant death, while enzyme dysfunction manifests in a variety of afflictions.<sup>19</sup> Four MPT enzymes have been found in plants.<sup>20</sup> (1) nitrate reductase (*see Reductase*) catalyzes the conversion of nitrate to nitrite, a key step in the assimilation of nitrogen, (2) aldehyde oxidase catalyzes steps in the formation of phytohormones such as abscisic acid and indole-3-acetic acid, (3) xanthine dehydrogenase is involved in ureide synthesis, purine catabolism, senescence, and oxidative stress response, and (4) sulfite oxidase is responsible for the detoxification of sulfite, produced during sulfur assimilation or from air pollution. Molybdenum deficiency in plants affects many species, causing poor vigor and chlorosis (yellowing) of the leaves, whereas Mo-MPT deficiency causes loss of function and death. The majority of Mo-MPT enzymes (including all those in the DMSO reductase family) are found in microbes. They are responsible for metabolic functions and the adaptation of the organism to available nutrient levels and environmental conditions.<sup>1-6</sup>

## 2.2 Classification and General Chemistry

The Mo-MPT enzymes are classified into two broad functional types: oxotransferases and hydroxylases (Figure 1). Oxotransferases catalyze oxygen atom transfer (*see Atom Transfer* and *Oxo Transfer*) (OAT) to (for oxidases) or from (for reductases) the central atom of simple oxoanions (*see Oxoanion*), and *S*- and *N*-oxides, employing water as the source or destination of active oxygen (\*O). The mediating role of molybdenum in oxygen transfer is obvious from equations (1) and (2), which combine to give the overall catalytic reaction in equation (3). The hydroxylases generally catalyze the insertion of an oxygen atom into C–H bonds of heterocyclic aromatic compounds and aldehydes, the oxygen atom again being derived from water (equation 4). The nature of the active oxygen atom varies by enzyme family (*vide infra*) as discussed in Sections 4–6. The enzyme reactions couple a two-electron net OAT process (equation 1) with sequential one-electron coupled electron-proton transfer (*see Proton Coupled Electron Transfer*) (CEPT) processes, centered on Mo/water and regenerating the active site (equation 2). Enzyme prosthetic groups (*see Prosthetic Group*) and physiological redox partners are responsible for electron transfer to or from the Mo center as required by equation (2).

The enzymes are subdivided into three families based on structural and sequence comparisons (Figure 1, Table 1).<sup>2</sup> Oxotransferases isolated from prokaryotes (*see Prokaryote*) belong to the DMSO reductase family. These enzymes include DMSO reductase, biotin *S*-oxide reductase, trimethylamine *N*-oxide reductase, dissimilatory nitrate reductase, formate

dehydrogenase, selenate reductase, and arsenite oxidase; they feature distorted trigonal prismatic  $[\text{Mo}^{\text{VI}}\text{O}(\text{AA})\text{L}_2]^-$  (AA = serinate, cysteinate, selenocysteinate, and so on; L = MPT-based ligand (*see Section 3*)) oxidized active sites (1). Some members of the DMSO reductase family, such as formate dehydrogenase and polysulfide reductase, catalyze reactions other than net OAT (*see Section 4*). Only two oxotransferases, sulfite oxidase and assimilatory nitrate reductase, have been identified in eukaryotes (*see Eukaryote*); they are members of the sulfite oxidase family and contain square-pyramidal  $\text{cis-}[\text{Mo}^{\text{VI}}\text{O}_2\text{L}(\text{cysteinate})]^-$  oxidized active sites (2) (*see Section 5*). The hydroxylases are all members of the xanthine oxidase family. These unique enzymes contain square-pyramidal  $[\text{Mo}^{\text{VI}}\text{OS}(\text{OH})\text{L}]^-$  oxidized active sites (3) featuring a catalytically essential terminal sulfido ligand (or bridged Mo–S–Cu) moiety. Again, several members of this family catalyze unusual reactions, including the conversion of CO to CO<sub>2</sub> by CO dehydrogenase, hydroxyl group transfer by pyrogallol transhydroxylase, and dehydroxylation by 4-hydroxybenzoyl-CoA reductase (*see Section 6*). The properties of selected enzymes are presented in Table 1.

## 3 MOLYBDENUM COFACTORS (Moco's) AND MPT LIGANDS

### 3.1 Moco's and the Structure and Function of MPT Ligands

The presence of a pterin-dithiolene (MPT-based) ligand at Mo is the unifying feature of the various molybdenum cofactors (Moco's) and enzymes.<sup>1–7</sup> The chemical nature of the pterin-dithiolene ligand was defined by degradative and spectroscopic studies performed by Rajagopalan, Johnson, and coworkers. They proposed the bicyclic structure (4) and

**Figure 1** Classification of Mo-MPT enzymes. Structures (1)–(3) represent oxidized active-site structures (only the dithiolene moiety of each MPT-based ligand is shown)

**Figure 2** Active site of *E. coli* nitrate reductase, showing pterin forms (4) and (5). Only the pterin-dithiolene portions of the MGD ligands are shown

suggested that the dithiolene unit functions as a bidentate ligand (*see Bidentate Ligand*) to Mo. This form was recently identified in *Escherichia coli* nitrate reductase (see Figure 2)<sup>21</sup> and was invoked to explain the electrochemical behavior of *R. capsulatus* xanthine dehydrogenase.<sup>18</sup> Subsequent X-ray crystal structures (*see Crystal Structures*)<sup>8–10</sup> confirmed the general validity of these proposals but revealed an unexpected tricyclic ‘pyranopterin’ form of the ligand (5; see also Figures 2, 3, 5, and 7). ‘Molybdopterin (MPT)’ was the name originally coined for the pterin-dithiolene ligand, but the fact that it contains no Mo and binds equally well to W has prompted calls for improved nomenclature. Metal-binding Pterin diThiolate<sup>4</sup> or Metal-binding pyranoPterin ene-1,2-diThiolate<sup>5</sup> have been proposed as alternative names allowing retention of the widely used MPT abbreviation (the former has the advantage of encompassing both ligand forms (4) and (5)). In prokaryotic enzymes, the phosphate

group of MPT is usually linked to the phosphate group of a 5'-nucleotide of cytidine, guanosine, adenosine, or inosine; these are commonly referred to as ‘dinucleotides,’ and are abbreviated, for example, as MGD (MPT-Guanosine Dinucleotide). Although conformationally flexible, MPT-based ligands adopt remarkably similar structures at enzyme active sites. In ubiquitous (5), the pyrazine and pyran rings of MPT are nonplanar, the three chiral (*see Chiral*) carbon atoms adopting the (*R*)-configuration. The pyran ring adopts a half-chair conformation and the mean planes defining the pterin and pyran moieties are related by an angle of ca. 40°. The polar groups of MPT (and any nucleotide appendage) are involved in an array of hydrogen bonds that anchor the ligand to the polypeptide chain. Crystallographic data are consistent with dihydropterin (4), or equivalent fully reduced tetrahydropterin (5) ligand redox levels.<sup>8–10</sup>

As well as its clearly established Moco-anchoring role, it is likely that the ‘noninnocent’ MPT ligand facilitates electron and proton transfer to and from the Mo center (possibly via structural changes modulating the covalency of the Mo–S bonds), the fine-tuning of redox potentials (*see Redox Potential*), and the buffering of oxidation state changes during turnover.<sup>1–7</sup>

### 3.2 Biosynthesis of MPT and Moco

#### 3.2.1 Molybdate Uptake and Storage

Molybdate is transported into bacteria (*see Bacteria*) and plants by low affinity pathways (on the back of Fe, phosphate, and sulfate uptake) and by specific proteins showing a high selectivity and affinity for [MoO<sub>4</sub>]<sup>2–</sup> over closely related oxoanions. Molybdate transport proteins, designated ModABC, are part of an ATP-binding cassette transporter in the periplasm. Inside the cell, so-called molbindins (Mop-type proteins) store molybdenum and regulate its uptake and utilization. The genes and proteins involved in molybdate transport, homeostasis, and regulation have been reviewed by Pau and Lawson<sup>22</sup> (*see also Metalloregulation*). Animals and humans require Mo as a trace element (*see Trace Element*) in their diets (*see Nutritional Aspects of Metals & Trace Elements*).

#### 3.2.2 Biosynthesis of MPT and Moco

The evolutionarily conserved Moco biosynthetic pathway consists of three steps (Scheme 1): (1) the conversion of a guanosine derivative (probably guanosine triphosphate) into sulfur-free Precursor Z via insertion of C-8 between the ribose C-2' and C-3' atoms, (2) sulfurization and transformation of Precursor Z into MPT, catalyzed by MPT-synthase, and (3) metal incorporation through chelation of the dithiolene moiety. Additional steps are involved in the attachment of a nucleotide to generate the dinucleotide forms found

Scheme 1

in bacteria. The biosynthetic pathway in *E. coli* has been extensively studied and many of the proteins involved have been structurally characterized. The multifunctional gephyrin protein is involved in Moco biosynthesis in mammalian and plant cells. The incorporation of the other (nonprotein) ligands at the Mo sites is not well understood; however, some of the enzymes responsible for the terminal sulfido ligand in hydroxylases have been identified. Moco deficiency in humans is a rare autosomal recessive condition marked by severe neurological abnormalities, ocular lens dislocation, and infant death.<sup>19</sup> The burial of Moco deep inside the holoenzymes implicates its incorporation prior to or during protein folding or aggregation, but the details of its incorporation remain unknown. Excellent reviews of Moco biosynthesis are available<sup>9,23</sup> (see also *Metalloreulation*).

#### 4 THE DIMETHYL SULFOXIDE (DMSO) REDUCTASE FAMILY

Enzymes in this family include DMSO reductase, biotin *S*-oxide reductase, dissimilatory nitrate reductase, trimethylamine *N*-oxide reductase, and formate dehydrogenase; they are found exclusively in bacteria and fungi and act as terminal respiratory reductases during anaerobic growth in the presence of their respective substrates.<sup>1-4,24,25</sup> DMSO reductases catalyze the reaction shown in equation (5); the water-soluble enzymes from the purple phototrophic bacteria *R. capsulatus* and *R. sphaeroides* are among the simplest Mo-MPT enzymes, being relatively small (ca. 85 kDa), single subunit

(see *Subunit*) enzymes with the Mo center as the only prosthetic group. In contrast, the DMSO reductase from *E. coli* is a heterotrimeric membrane-bound enzyme that couples via the quinol pool to nitrate reductase, thus producing a trans-membrane proton gradient for ATP synthesis. The production of dimethyl sulfide by bacteria in the world's oceans has a profound effect on marine life (influencing, e.g., the feeding behavior of sea birds) and global albedo (reflectance) and climate (through its role in cloud formation).<sup>26</sup>

The enzymes from *Rhodobacter* sp. have been isolated and crystallized under a variety of conditions. A number of crystal structures have revealed the presence of two MGD ligands, designated P and Q, a serinate-147 ligand, and a variable number of water-based ligands; pterin Q displays a range of complexation and redox modes as a result of sample degradation and active-site heterogeneity/disorder.<sup>8-10</sup> EXAFS<sup>27</sup> and resonance Raman<sup>28,29</sup> results provide strong evidence for the presence of distorted trigonal prismatic (see *Trigonal Prism*) monooxo-Mo(VI) (**1**) and square-pyramidal desoxo-Mo(IV) (see species (**c**) in Scheme 2) sites in the oxidized and reduced enzymes, respectively. The active site of the trimethylamine *N*-oxide from *Shewanella massilia* exhibits a closely related structure.<sup>9,10</sup> Substrate specificities in these and related enzymes are determined by the nature of the protein surface, substrate access channel, and the active-site pocket; side-chain (Tyr114 in DMSO reductases, Trp90 in *R. sphaeroides* biotin sulfoxide reductase) interactions with the oxo group, or their absence (in TMSO reductase), are particularly important in fine-tuning redox potentials.

(6)

There is strong evidence for a direct OAT mechanism for DMSO reductases. Schultz *et al.*<sup>30</sup> have demonstrated that *R. sphaeroides* dimethyl sulfoxide reductase catalyzes the reaction in equation (6), an archetypal OAT reaction in synthetic chemistry (Sections 7–9). An intermediate along the OAT reaction coordinate has also been structurally characterized in the form of DMSO-bound *R. capsulatus* DMSO reductase (see species (**d**) in Scheme 2), the DMSO being generated in the reaction of DMS with the terminal oxo ligand.<sup>9,10</sup> Structural data from other techniques (EXAFS, Raman, EPR) have also contributed to the consensus mechanism in Scheme 2. Here, the oxidized oxo-Mo(VI) site (**a** = (**1**)) undergoes CEPT reactions, via Mo(V) (**b**) forms, converting the oxo group to labile water with formation of the desoxo-Mo(IV) active site (**c**). DMSO interacts with (**c**) giving (**d**) – this facilitates direct OAT to produce reduced

Scheme 2

substrate (DMS) and regenerate the oxo-Mo(VI) site (a) (cf. Scheme 3).

Two types of dissimilatory nitrate reductases, localized in either the cytoplasmic membrane or the periplasm, are widespread among bacteria.<sup>1–5,25,31</sup> The cytoplasmic membrane-bound nitrate reductase (Nar) catalyzes the first steps of denitrification ( $\text{NO}_3^- \rightarrow \text{NO}_2^- \rightarrow \text{NO} \rightarrow \text{N}_2\text{O} \rightarrow \text{N}_2$ ) and nitrate ammonification ( $\text{NO}_3^- \rightarrow \text{NO}_2^- \rightarrow \text{NH}_3$ ). These reactions are the terminal electron-transfer reactions during anaerobic respiration, the enzymes being part of a redox loop generating a proton-motive force capable of driving ATP synthesis.<sup>25,31</sup> Periplasmic nitrate reductase (Nap) participates in cellular redox processes, aerobic denitrification, and nitrate scavenging.<sup>25,31</sup>

The heterotrimeric NarGHI from *E. coli* is composed of an Mo(MGD)<sub>2</sub> unit (NarG), an [Fe-S] cluster-containing electron-transfer unit (NarH), and a heme-containing membrane anchor (NarI). The Mo active site is remarkable in containing MGD in forms (4) and (5) and an unsymmetrically bound, bidentate Asp222 ligand (Figure 2).<sup>21</sup> The coupling of formate oxidation (by FdnGHI) and nitrate reduction (by NarGHI) by membrane-soluble menaquinol and/or ubiquinol drives proton translocation across the membrane.<sup>21,25</sup> The Asp222 ligand may function as an ambidentate ligand (see *Ambidentate Ligand*) during catalysis.

The periplasmic nitrate reductases are generally heterodimers, the larger unit (NapA, 90 kDa) binding catalytic Mo(MGD)<sub>2</sub> and [Fe<sub>4</sub>S<sub>4</sub>] centers and the small unit (NapB, 15 kDa) a pair of *c*-type heme groups. A membrane-anchored *c*-type cytochrome (NapC) uses the menaquinol pool to reduce the soluble NapAB complex. The X-ray structures of monomeric Nap from *D. desulfuricans* ATCC 27774 and heterodimeric NapAB from *R. sphaeroides* have been determined.<sup>9,10</sup> The trigonal prismatic oxidized Mo active sites are similar and contain two bidentate MGD ligands, an

amino acid thiolate donor (Cys140 and Cys152, respectively), and a water-based ligand. EXAFS studies are consistent with the presence of monooxo (1) and desoxy Mo (cf., species (c) in Scheme 2) centers in the oxidized Mo(VI) and reduced Mo(IV) forms of the enzyme, respectively. In these enzymes, nitrate is proposed to bind through oxygen to an Mo<sup>IV</sup>(Cys)(MGD)<sub>2</sub> center and undergo direct OAT via O–N bond cleavage, producing nitrite and an Mo<sup>VI</sup>O(Cys)(MGD)<sub>2</sub> center. Regeneration of the active site occurs through proton and electron-transfer processes leading to dissociation of water from the coordination sphere (cf. Scheme 2).

The structure of another member of this family, the selenocysteine-containing formate dehydrogenase H from *E. coli*, has also been determined; it contains an [Mo<sup>VI</sup>O(SeCys)(MGD)<sub>2</sub>]<sup>-</sup> oxidized active site (see *Selenium Proteins Containing Selenocysteine*).<sup>8–10</sup> Formate dehydrogenases catalyze the interconversion of formate and carbon dioxide and play an important role in global fixation of carbon dioxide.<sup>32</sup>

Enzymes catalyzing the oxidation of arsenite (AsO<sub>3</sub><sup>3-</sup>) to arsenate (AsO<sub>4</sub><sup>3-</sup>) have been identified or isolated from archaea, bacteria, and algae. The active site of arsenite oxidase from *Alcaligenes faecalis*<sup>9,10</sup> contains inequivalent P and Q pterins and two nonpeptide ligands, proposed to be oxo and hydroxo ligands on the basis of EXAFS studies.<sup>33</sup> *Chrysiogenes arsenatis* respire anaerobically using arsenate as the terminal electron acceptor and acetate as electron donor. Reduction of arsenate to arsenite is effected by a periplasmic heterodimeric enzyme, arsenate reductase. Enzymes metabolizing analogous selenium-containing species are also known.<sup>2,3</sup>

Reductive cleavage of sulfur–sulfur bonds in inorganic sulfur species is exploited in terminal electron transfer in some bacteria. The tetrathionate and thiosulfate reductases of the enteric bacterium *Salmonella enterica* LT2 and the polysulfide reductase of the rumen bacterium *Wolinella succinogenes* effect such reactions.<sup>24</sup>

## 5 THE SULFITE OXIDASE FAMILY

This family includes the sulfite oxidases and dehydrogenases of prokaryotes (*Thiobacilli* sp.), plants, birds, and animals, and the assimilatory nitrate reductases from bacteria, algae, fungi, and plants.<sup>1–5,24</sup> The sulfite oxidases of higher eukaryotes are 100–110 kDa homodimers (Table 1); they are located in the mitochondrial intermembrane space and catalyze the oxidation of toxic sulfite to innocuous sulfate (equation 7). Human sulfite oxidase deficiency leads to major neurological abnormalities, mental retardation, dislocation of the ocular lenses, and early death.<sup>19</sup>

The crystal structure of chicken liver sulfite oxidase revealed a five-coordinate, square-pyramidal (*see Square Pyramidal*) Mo center coordinated by a bidentate MPT ligand, a cysteine thiolate (from Cys185, conserved in all active enzymes from this family), and two O-donor ligands (Figure 3).<sup>9,10</sup> EXAFS<sup>34</sup> and resonance Raman<sup>35</sup> studies indicate the presence of two oxo ligands in the oxidized enzyme ( $\nu(\text{MoO}_2)$  903, 881  $\text{cm}^{-1}$ ); only one of these is exchanged into  $\text{H}_2^{18}\text{O}$  buffer during redox cycling, the other being retained in Mo(V) and Mo(IV) forms. Paramagnetic resonance studies have defined the pH dependent nature of the active site and various anion (*see Anion*) bound forms of the enzyme.<sup>24</sup> The types of centers formed under various conditions are shown in Figure 4.

Comprehensive laser flash photolysis studies on chicken and human SO have probed the rates of *intermolecular* electron transfer (IET, *see Intermolecular*) between the Mo and heme centers. Data are consistent with a CEPT mechanism interconverting  $\text{Fe}^{\text{II}}/[\text{MoO}_2]^{2+}$  and  $\text{Fe}^{\text{III}}/[\text{MoO}(\text{OH})]^+$  centers. To account for the wide range of IET rates (20–1400  $\text{s}^{-1}$ ), it has been proposed that protein conformational changes effectively gate IET by changing the  $\text{Fe} \cdots \text{Mo}$  distance.<sup>24,36</sup>

The existence of sulfite oxidase in plants such as *Arabidopsis thaliana* (wall or thule cress), tobacco, pea, spinach, barley, carrot, and poplar trees has now been confirmed,<sup>37</sup> and the enzyme from *A. thaliana* has been structurally characterized.<sup>38</sup> The homodimeric, peroxisomal enzyme lacks the heme domain observed in animal sulfite oxidases, making it the simplest Mo-MPT enzyme yet isolated from eukarya. The animal and plant sulfite oxidases have an overall 47% sequence identity. The detoxification of sulfite, produced in the assimilation of sulfate into sulfur-containing amino acids and membrane components (sulfatides) and from environmental sources (acid rain), is also the principal role of the plant enzymes.

**Figure 3** Active site of chicken liver sulfite oxidase. The apical group is a terminal oxo ligand, the second oxygen is an oxo ligand in the oxidized enzyme

**Figure 4** Important active-site states of sulfite oxidase

Assimilatory nitrate reductases catalyze the first step of nitrate assimilation by bacteria, fungi, algae, and plants (equation 8; Reductant: NADH in plants and most algae, NADPH in fungi); they are estimated to transform ca.  $10^7$  tons of inorganic nitrogen per year, as a prelude to nitrogen incorporation into proteins and nucleic acids.<sup>1–5,25,31</sup> Eukaryotic assimilatory nitrate reductases are cytosolic homodimers (ca. 220 kDa) containing one *b*-type cytochrome, one FAD, and one Mo-MPT center per subunit (Table 1). Two types of assimilatory nitrate reductases, ferredoxin/flavodoxin- and NADH-dependent (Nas) enzymes, are found in bacteria; these cytosolic enzymes contain Mo-MGD and Fe/S groups but not the heme groups found in eukaryotic enzymes. EPR and EXAFS studies of chicken liver sulfite oxidase and *Chlorella vulgaris* nitrate reductase indicate that both enzymes possess similar active sites.<sup>25,31</sup>

With respect to the molybdenum center, it appears that a spectator oxo ligand (*see Spectator Ligand (Ion)*) controls the electronic structure allowing the second oxo ligand to participate in OAT reactions with the substrate (*see Substrate*),  $\text{X} = \text{SO}_3^{2-}$  for sulfite oxidase (Scheme 3, **a**  $\rightarrow$  **b**); the substrate enters the enzyme via a substrate (solvent) access channel directed toward the exchangeable oxo group. Egress of the oxidized substrate,  $\text{XO} = \text{SO}_4^{2-}$ , permits the

**Scheme 3**

generation of an *aqua*-Mo(IV) (see *Aqua*) species (**b** → **c**) that undergoes CEPT reactions leading to the regeneration of the active site (**c** → **d** → **a**).<sup>1-4,24</sup> Nitrate reductases would cycle in the opposite direction (cf. Scheme 2 for dimethyl sulfoxide reductase).<sup>1-4,25</sup> The OAT chemistry is represented as a concerted two-electron event, the CEPT chemistry as two consecutive ( $e^-$ ,  $H^+$ ) transfers. Other possible mechanisms involve oxoanion binding to Mo prior to OAT or attack of sulfite by activated water (or hydroxide) within the active-site pocket.<sup>2-4,24</sup>

## 6 THE XANTHINE OXIDASE FAMILY

These enzymes (hydroxylases) are distributed across all phyla and include xanthine oxidoreductase (see *Oxidoreductase*) (oxidase and dehydrogenase),<sup>1-5,39-41</sup> aldehyde oxidoreductase,<sup>1-5,41,42</sup> and a host of lesser known enzymes like 4-hydroxybenzoyl-CoA reductase,<sup>2-4</sup> pyrogallol transhydroxylase,<sup>2-4</sup> picolinate dehydrogenase,<sup>39</sup> CO dehydrogenase,<sup>32</sup> and various quinoline<sup>43</sup> and nicotinate oxidoreductases.<sup>44</sup> They generally catalyze net OAT reactions through the insertion of an oxygen atom into a C–H bond in aromatic heterocycles (e.g., purines, pyrimidines, pterins) and aldehydes, yielding hydroxylated products and carboxylic acids, respectively. Some enzymes catalyze the translocation of hydroxy groups on aromatic substrates and many are selenium-dependent.<sup>45</sup>

The xanthine oxidoreductases are large, complex molybdo-flavoproteins with roles in the catabolism of purines, for example, oxidizing hypoxanthine to xanthine and xanthine to uric acid (equation 9).<sup>39-41</sup> Xanthine oxidase can also catalyze the reduction of nitrate to nitrite (or in the presence superoxide, peroxynitrite) and the reduction of nitrite to nitric oxide. Peroxynitrite, a powerful and destructive oxidant, has been implicated in diseases such as arthritis, atherosclerosis, multiple sclerosis, and Alzheimer's and Parkinson's diseases. The microbicidal role of milk and intestinal xanthine oxidase may also involve the generation of peroxynitrite in the gut. The high levels of the enzyme in the mammary glands of pregnant

or lactating animals suggests a possible role for xanthine oxidoreductases in mammogenesis and lactogenesis.<sup>41</sup> A genetic deficiency of xanthine dehydrogenase leads to the rare but benign condition of xanthinuria (type 1) in humans, whereas enzyme overactivity is associated with hyperuricemia and gout. Allopurinol, a drug for these conditions, acts to suppress xanthine dehydrogenase activity. An excellent review of the potential pathophysiological roles of xanthine oxidase has been prepared by Harrison.<sup>46</sup>

Aldehyde oxidases oxidize azaheterocycles and aldehydes and are involved in the biosynthetic pathways producing retinoic acid and various phytohormones including abscisic acid and indole-3-acetic acid. Aldehyde oxidase and xanthine dehydrogenase both play vital roles in the metabolism of drugs and pollutants, for example, in the metabolism of famciclovir to the antiviral agent penciclovir. Aldehyde oxidoreductase is also important in the metabolism of alcohol (following its transformation to acetaldehyde) and the antimigraine agent almotriptan.<sup>42,46</sup>

The cytosolic, mammalian hydroxylases are homodimeric, with three distinct binding domains for  $[\text{Fe}_2\text{S}_2]$  (20 kDa, N-terminus), FAD (40 kDa), and Mo-MPT (85 kDa, C-terminus) centers.<sup>39-42</sup> Mammalian xanthine oxidoreductases exist in two interconvertible forms, a dehydrogenase (dominant in vivo) employing  $\text{NAD}^+$  as electron acceptor and an oxidase employing dioxygen as electron acceptor; the dehydrogenase/oxidase transformation is induced by proteolytic cleavage or cysteine modification.<sup>47</sup> The generation of superoxide and hydrogen peroxide by xanthine oxidase is believed to be responsible for tissue damage due to postischemic reperfusion injury. The avian and bacterial (*R. capsulatus*) enzymes are stable dehydrogenases. The xanthine dehydrogenase from *R. capsulatus* is unusual for a bacterial Mo-MPT enzyme in that it contains MPT (as in eukaryotic enzymes) rather than a nucleotide derivative.

The presence of a catalytically essential active-site sulfur atom was demonstrated by cyanide deactivation/sulfide reactivation studies performed around 1970. In the 1980s, EXAFS revealed the presence of terminal oxo ( $\text{Mo}=\text{O} = 1.73 \text{ \AA}$ ) and terminal sulfido ( $\text{Mo}=\text{S} = \text{ca. } 2.15\text{--}2.18 \text{ \AA}$ ) ligands, as well as two additional sulfur donor atoms. Enzymes from a number of sources have now been structurally characterized (Table 1). These include bovine milk xanthine dehydrogenase and its BOF-4272-inhibited form, the active and alloxanthine-inhibited xanthine dehydrogenase from *R. capsulatus*, the aldehyde oxidoreductases from *D. gigas* and *D. desulfuricans*, and the CO dehydrogenases from *Oligotropha carboxidovorans* and *H. pseudoflava*.<sup>8-10</sup> Crystallographic and spectroscopic data together indicate the presence of five-coordinate, square-pyramidal (or pseudotetrahedral (see *Tetrahedral*))  $[\text{Mo}^{\text{VI}}\text{OS}(\text{OH})_n(\text{MPT})]^{0/-}$  ( $n = 1, 2$ ) oxidized active sites. Resonance Raman studies have allowed the assignment of bands at  $899$  and  $474 \text{ cm}^{-1}$  to  $\nu(\text{Mo}=\text{O})$  and  $\nu(\text{Mo}=\text{S})$ , respectively; the oxo O atom is nonlabile.<sup>48</sup> Crystallographic evidence supports the presence of an apical terminal

**Figure 5** The active site of *D. gigas* aldehyde oxidoreductase. An apical sulfido group is indicated by crystallographic studies but its position remains ambiguous. Although labeled as a hydroxy group, the second oxygen donor may be an aqua ligand. Only the pterin-dithiolene portion of the MCD ligand is shown

sulfido ligand in the square-pyramidal description (Figure 5), but the oxo ligand may in fact be the apical ligand (Figure 6, cf. position of ligand S in CO dehydrogenase (Figure 7)). (Evidence of an equatorial sulfido group has been presented by Okamoto *et al.* Proc. Natl. Acad. Sci. U.S.A., 2004, 101, 7931). The Very Rapid EPR signal of xanthine oxidase ( $t_{1/2} \sim 10$  ms) appears during turnover under substrate *limiting* conditions and is assigned to an  $[\text{Mo}^{\text{V}}\text{OS}(\text{urate})(\text{MPT})]^{2-}$  species on the basis of  $^{17}\text{O}$  and  $^{33}\text{S}$  superhyperfine and  $^{13}\text{C}$ -8 ENDOR coupling data (see Section 11.2).<sup>1,40</sup> The unpaired electron is highly delocalized, with ca. 35% sulfido ligand character. In the presence of *excess* substrate, the Rapid signal also appears;  $^1\text{H}$  and  $^{33}\text{S}$  superhyperfine coupling data suggest the presence of an  $[\text{Mo}^{\text{V}}\text{O}(\text{SH})]^{2+}$  center. The presence of bound urate in the Mo(IV) state has been inferred from EXAFS and resonance Raman studies; an  $[\text{Mo}^{\text{IV}}\text{O}(\text{SH})(\text{urate})(\text{MPT})]^{2-}$  center is postulated.<sup>1,40</sup> The detection of intermediates during a *single* catalytic turnover of xanthine oxidase shows that the oxygen atom transferred to substrate originates from the enzyme center and not directly from solvent water.<sup>49</sup> Proposed structures

**Figure 6** Important active-site states of xanthine oxidoreductase

for the important states of active xanthine oxidase are shown in Figure 6. The mechanism shown in Scheme 4 is supported by many lines of evidence but is not the only one possible.<sup>2,4,40</sup> Outstanding mechanistic questions include the nature of the active oxygen, the role of the terminal oxo and thio ligands, and the choreography of proton and electron transfer.

The carbon monoxide dehydrogenase from aerobic, carboxidotrophic bacteria catalyzes the oxidation of CO to  $\text{CO}_2$ , and thereby contributes to the maintenance of subtoxic concentrations of CO in the lower atmosphere. The enzymes are included in the xanthine oxidase family because of sequence similarities and their conversion to inactive ‘desulfo’ (and/or ‘decupro’) forms upon cyanolysis. However, and quite remarkably, the CO dehydrogenase from the bacterium *O. carboxidovorans* (formerly *Pseudomonas carboxidovorans*) contains an  $\{(\text{MCD})\text{Mo}^{\text{VI}}(=\text{O})(\text{OH})(\mu\text{-S})\text{Cu}^{\text{I}}(\text{S-Cys388})\}$  active site featuring an unprecedented Mo–S–Cu unit (Figure 7).<sup>10,50</sup> The

**Figure 7** The active site of *O. carboxidovorans* CO dehydrogenase. Although labeled as a hydroxy group, the second oxygen donor may be an aqua ligand. Only the pterin-dithiolene portion of the MCD ligand is shown

**Scheme 4**

five-coordinate, square-pyramidal Mo center closely resembles that of active xanthine oxidase, with an oxo ligand in the *apical* site and a longer (as expected) Mo–( $\mu$ -S) distance; the geometry at the Cu(I) center is close to linear. The presence of the binuclear heterometallic unit has been confirmed by complementary EXAFS studies.<sup>51</sup> A mechanism involving a thiocarbonate intermediate formed by cooperative binding of the polar CO molecule by the two metal centers has been proposed.

## 7 SYNTHETIC ANALOGUE CHEMISTRY

### 7.1 The Contribution of Synthetic Analogues

The synthetic analogue or model approach provides insights into bioinorganic systems through the synthesis and study of closely related ‘model’ compounds. It garners structural, electronic, spectroscopic, and chemical information crucial to a complete understanding of enzyme behavior.<sup>4,52</sup> This section begins with some general observations relating to biologically relevant ligands and OAT and CEPT reactions. Selected chemistry relating to specific enzyme families is then presented. An exhaustive review of mononuclear Mo chemistry can be found in *Comprehensive Coordination Chemistry II*<sup>53</sup> (see also *Molybdenum: Inorganic & Coordination Chemistry*).

### 7.2 Ligands Important in Biomolybdenum Chemistry

#### 7.2.1 Ligands Derived from Water: Oxo, Hydroxo, Aqua

High-valent molybdenum chemistry is dominated by oxo complexes.<sup>53</sup> The terminal oxo group is characterized by multiple bonding (one  $\sigma$  and up to two  $\pi$  components) to the metal, a short Mo=O distance (1.64–1.72 Å), and group-specific IR absorptions. The strong trans influence (see *Trans Influence*) of the oxo ligand is responsible for lengthening (by 0.15–0.3 Å) or disfavoring *trans* Mo–L interactions. Complexes containing *fac*-MoO<sub>3</sub>, *cis*-[MoO<sub>2</sub>]<sup>2+</sup>, and [MoO]<sup>4+</sup> units are common in oxo-Mo(VI) chemistry. Dioxo complexes are very common and tetrahedral, trigonal bipyramidal, and (in the main) distorted octahedral (see *Octahedral*) geometries are observed. Seven-coordinate, pentagonal bipyramidal (see *Pentagonal Bipyramid*) peroxo complexes currently constitute the largest class of monooxo-Mo(VI) complexes. A wide variety of O-, N-, S-, and mixed-donor ligands serve as coligands in these oxo complexes. Mononuclear Mo(V) and Mo(IV) complexes generally contain a single oxo group and exhibit square-pyramidal or distorted octahedral structures. The highly reactive *cis*-dioxo-Mo(V) complexes, [(L-N<sub>2</sub>S<sub>2</sub>)MoO<sub>2</sub>]<sup>–</sup> and [Tp\*MoO<sub>2</sub>X]<sup>–</sup> (see (6) and (7) for ligand structures), are

rare exceptions (but EPR signals from such centers have never been observed in enzymes). In the absence of steric protection, Mo(V) complexes exhibit a marked tendency for di- or polynucleation reactions. The chemical reactions of oxo-Mo(VI–IV) complexes have been extensively reviewed.<sup>53,54</sup>

(6) L-N<sub>2</sub>S<sub>2</sub>

(7) Tp\*: R = R' = Me

Tp<sup>Pr</sup>: R = *i*Pr, R' = H

Mo-MPT enzymes mediate formal exchange of an oxygen atom between the substrate and water (equation 3), and at some stage water is bound to the Mo center. CEPT reactions are responsible for the interconversion of aqua, hydroxo, and oxo ligands upon the oxidation state change; hydroxo ligation is inferred from enzyme EPR spectra, but direct evidence for aqua ligation is lacking. Aqua(oxo) complexes, exemplified by *cis*-Mo<sup>VI</sup>O<sub>2</sub>(OH)<sub>2</sub>Cl<sub>2</sub>, [Mo<sup>V</sup>OX<sub>4</sub>(OH<sub>2</sub>)]<sup>–</sup>, and [Mo<sup>IV</sup>O(OH<sub>2</sub>)(dppe)<sub>2</sub>]<sup>+</sup>, generally possess *trans* aqua(oxo) arrangements. However, certain coligands can induce a *cis* geometry, as observed in six-coordinate (L-N<sub>2</sub>S<sub>2</sub>)MoO(OH) and Tp\*MoO(OH)X (X = monodentate anion).<sup>53</sup>

(8)

#### 7.2.2 Sulfur Ligands

The Mo–S linkages shown in (8) are found at the active sites of Mo–MPT enzymes. Dithiolene, thiolate, and hydrosulfido complexes are known for all common Mo oxidation states, although the latter are extremely rare; terminal thio ligation is restricted to Mo(VI–IV) complexes.<sup>53</sup> Metallodithiolenes have been extensively studied and reviewed.<sup>7,53</sup> Biologically relevant dithiolene complexes feature two types of ligands: arene-1,2-dithiolates (where the ‘ene’ function is part of an aromatic ring) and authentic dithiolenes (see Sections 9 and 10). Two structural motifs are encountered in ternary oxo bis(dithiolene)-Mo complexes. Firstly, distorted octahedral geometries are observed for *cis*-dioxo-Mo(VI) complexes; here, the longest Mo–S distances (ca. 2.6 Å vs 2.4 Å) are *trans* to the terminal oxo ligands (*d*(Mo=O) = 1.70–1.73 Å). Secondly, square-pyramidal complexes with apical oxo

ligands are characteristic of both Mo(V) and Mo(IV) complexes.<sup>53</sup> The study of these and related complexes is relevant to the modeling of the DMSO reductase family of enzymes (see Sections 7.3 and 9.1). Mono(dithiolene) complexes relevant to the other two enzyme families are still quite rare and generally do not participate in clean OAT reactions.<sup>53</sup> Very recent progress in this area is described in Section 10.

The synthesis of Moco's (Mo-MPT complexes) presents significant challenges, however, progress is being made.<sup>4,52,55</sup> A general strategy for the synthesis of asymmetrically substituted dithiolenes, involving the generation of dimethylamino- or thione-protected 1,3-dithiolates and their subsequent deprotection by alkaline hydrolysis (Scheme 5), has been developed by Garner, Joule, and coworkers. In the presence of  $[\text{MoO}_2(\text{CN})_4]^{4-}$ , square-pyramidal oxo-Mo(IV) complexes of the type  $[\text{MoO}(\text{dithiolene})_2]^{2-}$  are formed (R = phenyl, pyridyl, quinoxaliny, or pterinyl derivatives). These are stepping stones to Mo(V) complexes and may serve as precursors to the Mo(VI) species.<sup>55</sup> The reactions of alkynes with polysulfido complexes (*EIC-1*)<sup>1</sup> or  $\alpha$ -bromo ketones with  $\text{Cp}_2\text{Mo}(\text{SH})_2$ ,<sup>56</sup> have also been exploited in the synthesis of unsymmetrical dithiolenes, including some pterin derivatives. Some of these undergo oxidative decomposition producing molecules closely related to urothione, the excretory by-product of MPT degradation.

Investigations by Enemark, Kirk, and coworkers have provided insights into the electronic structure and function of dithiolene- and thiolato-Mo complexes and Mo-MPT enzymes.<sup>7</sup> For example,  $\text{Tp}^*\text{MoOL}$  (L = arene dithiolate, e.g., benzene-1,2-dithiolate (bdt)) and related nitrosyl complexes feature a highly covalent, three-center, pseudo- $\sigma$  bonding interaction between the redox-active Mo  $\phi_{xy}$  and S (dithiolene) in-plane  $\phi^{a'}$  orbitals; this interaction is optimized when the strong-field ligand is cis and perpendicular to the  $\text{MoS}_2$  plane. A  $\pi$  interaction between the Mo  $\phi_{xy}$  and S  $\phi^{a'}$  out-of-plane orbitals is also possible depending on the electronic requirements of the metal; here, the degree of orbital interaction is determined by the fold angle of the Mo-dithiolene unit along the  $\text{S} \cdots \text{S}$  vector. The redox potentials

and rates of electron transfer to or from enzyme Mo-MPT centers may be controlled by variations in interactions of this type.<sup>7,57</sup> Related studies have defined the covalency and electronic structures of thiolate complexes, including known  $[\text{MoO}(\text{SR})_4]^{-58,59}$  and  $(\text{L-N}_2\text{S}_2)\text{MoO}(\text{SR})^{60}$  complexes.

Only a handful of pseudotetrahedral or octahedral oxosulfido-Mo(VI) and -Mo(V) complexes are known, and their chemistry is described in Section 11. Mononuclear sulfido-Mo(V) complexes are unstable due to their susceptibility to redox, polynucleation, and hydrolysis reactions. Trispyrazolylborate derivatives such as structurally characterized  $\text{Tp}^*\text{Mo}^V\text{SX}_2$  (X = Cl, OPh derivative;  $\text{X}_2$  = bdt, catecholate) are most commonly encountered. The  $\text{Tp}^*$  complexes exhibit short Mo=S bonds (ca. 2.13 Å), intense  $\text{S}(1s) \rightarrow \pi^*$  (Mo=S) XAS transitions characteristic of terminal thio ligands, and EPR  $g_{\text{iso}}$  (see *g-Factor*) values substantially lower than their oxo analogues.<sup>53</sup>

Speculation about the precise roles of active-site sulfur is tempered by an appreciation of the redox versatility and interplay of sulfur and molybdenum. This is evident from synthetic systems, where the catenation of sulfur (with attendant redox and/or ligand elaboration) and induced internal electron-transfer reactions are frequently observed. The redox interplay of Mo and S, reflected in 'undesirable synthetic outcomes,' may prove crucial to a full description of enzyme behavior.<sup>61,62</sup> (see also *Sulfur: Inorganic Chemistry*)

### 7.3 Atom Transfer Chemistry

Molybdenum has a marked predilection for OAT reactions<sup>53</sup> and biomimetic systems have been reviewed.<sup>54</sup> OAT is a concerted two-electron process that results in the oxidation of the oxygen atom acceptor and the reduction of the donor. The most common reactions for Mo are shown in equations (10) and (11). Catalysis results from the coupling of these reactions, leading to net oxidation of X by  $\text{X}'\text{O}$  (equation 12, cf. equation 6). Transformations involving oxo-Mo(VI) and desoxo-Mo(IV) complexes are recent and important developments (see Section 9).

Comproportionation and concomitant formation of  $\mu$ -oxo (see  *$\mu$ -Oxo Bridge*)-Mo(V) species (equation 13) is a prevalent complication in Mo OAT chemistry; the formation of dinuclear (see *Dinuclear*) complexes can be reversible or irreversible, allowing access to both Mo(IV) and Mo(V) complexes or only Mo(V) species, respectively.<sup>54</sup>

For neutral complexes, comproportionation is usually encountered when L is not sufficiently bulky to prevent close

Scheme 5

approach of the Mo atoms. Complexes containing dithio acid, cysteine ester (CysOEt), tridentate Schiff base (hpd), and 2,6-bis(2,2-diphenyl-2-thioethyl)pyridine(2-) (L-NS<sub>2</sub>) ligands readily participate in comproportionation/dinucleation reactions.<sup>54</sup> Dinucleation must be prevented in the development of valid enzyme models and steric, electrostatic, and/or immobilizing strategies have been successful in this regard. Comproportionation to monomeric Mo(V) species is also observed but this can be controlled and exploited to produce models for the EPR-active Mo(V) states of enzymes.<sup>54</sup>

The ligands Tp\* (and derivatives) (7), 2,2-diphenyl-2-mercaptoethanoate(2-) (L-SO), bis(4-*t*-butylphenyl)-2-pyridylmethanethiolate(1-) (L-NS), and various dithiolenes support clean OAT reactions between monomeric species (equations 10 and 11); the reactions have been extensively studied by kinetic methods (*see Kinetic Methods*).<sup>54</sup> The rate constants for these reactions span a ca. 10<sup>6</sup> range depending on the nature of the substrate and ligand (Table 2). In substrate oxidation reactions (equation 10), phosphines feature prominently as oxygen atom acceptors (X). Generally, these reactions are first order in both the phosphine and Mo complex; they are proposed to proceed by an associative mechanism involving nucleophilic attack of the phosphine lone pair on the  $\pi^*$  Mo=O orbital. Theoretical studies have shown these reactions are facilitated, both electronically and energetically, by the presence of a ‘spectator oxo group,’ and phosphine oxide intermediates have now been isolated and structurally characterized.<sup>63</sup> The mechanism of sulfite oxidation by dioxo-Mo(VI) complexes is less certain (*see* Section 10.2).

A much broader range of substrates is amenable to reduction by oxo-Mo(IV) complexes (equation 11). These include many biological substrates such as S- and N-oxides and nitrate, and species related to selenate and arsenate. These reactions are also first order in both the substrate and metal complex; they are proposed to proceed by associative mechanisms involving coordination of substrate to Mo and concomitant OAT.<sup>54</sup> A thermodynamic scale for OAT reactions has been described by Holm and Donahue.<sup>64</sup>

More recently, simple complexes such as MoO<sub>2</sub>X<sub>2</sub> (DMSO)<sub>2</sub> (X = Cl, Br), (PPh<sub>4</sub>)<sub>2</sub>[MoO<sub>2</sub>(NCS)<sub>4</sub>], MoO<sub>2</sub>

(NCS)<sub>2</sub>(Bu<sub>2</sub>bpy), and MoO<sub>2</sub>(acac)<sub>2</sub> have been shown to catalyze OAT without apparent comproportionation.<sup>54</sup> These observations have challenged the accepted ‘design criteria’ for efficient OAT catalysis.

#### 7.4 Coupled Electron-proton Transfer (CEPT) Reactions

Regeneration of enzyme active sites is proposed to take place via two one-electron CEPT reactions, accounting for the detection of EPR-active Mo(V) enzyme states. CEPT reactions are facilitated by the quite general interconversion of water-based (oxo, hydroxo, aqua) ligands induced by changes to the oxidation state of the metal. Related transformations interconverting thio and hydrosulfido coligands at oxo-Mo centers are envisaged in hydroxylases. The electron density at the metal center is communicated to the donor oxygen atom via the  $\pi$ -bonding framework; reduction of the center increases the basicity and level of protonation (*see Protonation*) of oxygen while oxidation decreases the basicity and level of protonation of oxygen. While detailed mechanistic information is often lacking, CEPT processes remain the most logical explanation for many synthetic outcomes and the generally irreversible reduction of high-valent oxo-Mo species.<sup>53</sup> The stoichiometries of the synthetic reactions represented by equations (14), (15), and (16) (E = electrophile (*see Electrophile*) (H<sup>+</sup>, SiMe<sub>3</sub>), *vide infra*) are well established and hint at CEPT or, more broadly, coupled electron-electrophile transfer (CEET) processes.<sup>1</sup> The literature should be consulted for a full overview of OAT and CEPT reactions.<sup>4,53,54</sup>

## 8 A COMBINED OAT/CEPT MODEL

The Mo-Tp\* and Mo-Tp<sup>Pr</sup> chemistry summarized in Scheme 6 represents a unique, holistic model of an important paradigm in Mo-MPT enzymes, the coupling of OAT and CEPT reactions during substrate turnover.<sup>54,65</sup>

The complexes *cis*-Tp\*Mo<sup>VI</sup>O<sub>2</sub>X (X = halide, monoanionic O-, N- or S-donor) react with PPh<sub>3</sub> to produce OPPh<sub>3</sub> and a variety of Mo-containing products, depending on the conditions (particularly the solvent) of the reaction (see Table 2 for rate constants); oxo-Mo(IV) complexes, Tp\*MoOX(solv), are generated when coordinating solvents like dmf, MeCN, and pyridine are employed (cf. equation 1). Both types of complexes exhibit six-coordinate octahedral structures, as exemplified by the structure of Tp\*MoO<sub>2</sub>(SPh) in Figure 8. Complexes containing ambidentate dithiophosphate and -phosphinate complexes undergo similar reactions, the dithio ligands being monodentate and bidentate in the dioxo-Mo(VI) and oxo-Mo(IV) species, respectively.<sup>54</sup> An associative mechanism, in which the nucleophilic phosphine attacks a terminal oxo ligand, is supported by kinetics and computational studies.<sup>54,66</sup> The phosphine oxide intermediates in such reactions have now been isolated and structurally

characterized.<sup>63</sup> The oxo-Mo(IV) complexes react with a variety of S- and N-oxides and nitrate to reform the dioxo-Mo(VI) species and catalyze the oxidation of phosphines by S- and N-oxides (equation 12, cf. equation 6).

One-electron redox processes (effected electrochemically or chemically) permit Mo(V) states to be accessed and facilitate the coupling of the two-electron OAT reactions to (regenerative) one-electron CEPT reactions. The dioxo-Mo(VI) complexes undergo electrochemically reversible one-electron reductions producing dioxo-Mo(V) species, for example, [Tp\*MoO<sub>2</sub>X]<sup>-</sup>, characterized by broad and anisotropic EPR spectra; these are readily protonated to give Tp\*MoO(OH)X, which feature less-anisotropic doublet EPR signals (due to <sup>1</sup>H superhyperfine coupling) similar to those exhibited by enzymes. Chemical reduction permits the isolation of salts such as CoCp<sub>2</sub>[Tp\*MoO<sub>2</sub>(SPh)], Tp\*MoO(OH)(SPh) and derivatives of the type Tp\*MoO(OSiMe<sub>3</sub>)X. The dioxo-Mo(V) complexes support a variety of one-electron processes but do not participate in two-electron OAT reactions.

The generation of oxo(hydroxo)-Mo(V) species, for example, Tp\*MoO(OH)X, in the reactions of Tp\*MoO<sub>2</sub>X with half an equivalent of PPh<sub>3</sub> in wet solvents is interpreted in terms of combined OAT/CEPT reactions. Thus, water is an effective ligand for the binding site of putative Tp\*MoOX, formed upon OAT from Mo to phosphine, and unreacted Tp\*MoO<sub>2</sub>X is an effective oxidant for Tp\*MoOX(OH<sub>2</sub>). Hence, comproportionation (equation 17) mimics oxidation of reduced enzymes by external oxidants.<sup>54</sup>

Combined with the ready autoxidation (*see Autoxidation*) of the oxo(hydroxo) complex, it is possible to effect the catalytic aerial oxidation of substrates with this system. <sup>18</sup>O and <sup>17</sup>O-labeling studies have confirmed that the oxygen atom transferred to PPh<sub>3</sub> comes from Tp\*MoO<sub>2</sub>X, and that like the enzyme systems water, not dioxygen, is the source of active oxygen. Overall, the oxidation of PPh<sub>3</sub> by Tp\*MoO<sub>2</sub>X in wet aerobic solvents is represented by equation (18) (cf. equation 3).<sup>65</sup> An OAT/CEPT system interconverting monooxo and desoxo complexes, viz, [Tp\*Mo<sup>VI</sup>OX<sub>2</sub>]<sup>+</sup> to [Tp\*Mo<sup>IV</sup>(OPPh<sub>3</sub>)X<sub>2</sub>]<sup>+</sup> (thence to [Tp\*Mo(OH<sub>2</sub>)X<sub>2</sub>]<sup>+</sup>), is under development by Basu and coworkers.<sup>67</sup>

## 9 MODELS FOR THE DMSO REDUCTASE FAMILY

### 9.1 Functional Models

The OAT reactions of bis(dithiolene) complexes are of interest from a biological perspective (nb. DMSO reductase

Scheme 6

Figure 8 Structure of Tp\*MoO<sub>2</sub>(SPh)

enzymes); here, comproportionation and dinucleation appear to be prevented by electrostatic factors.<sup>54</sup> Dioxobis(dithiolene) complexes react with oxygen atom acceptors (X) according to equation (10), and kinetics data are available for the reactions of  $[\text{MoO}_2(\text{bdt})_2]^{2-}$  with  $\text{PPh}_3$ <sup>68</sup> (Table 2) and  $(\text{NBu}_4)_2[\text{MoO}_2(\text{mnt})_2]$  ( $\text{mnt} = 1,2\text{-dicyanoethenedithiolate}$ ) with  $\text{HSO}_3^-$  (Section 10.2), phosphites,<sup>69</sup> and phosphines<sup>70</sup> (Table 3). For phosphine reactions, OAT rates increase as the basicity of the substrate increases (inversely to the parameter  $\chi$ ; see Table 3). The rate ratio  $k_{\text{Mo}}/k_{\text{W}}$  of ca.  $10^2\text{--}10^3$  (Table 3) indicates that Mo complexes are more effective oxidants than their W analogues; the same is true of Mo-MPT enzymes and their W analogues (see *Tungsten Proteins*).<sup>55,71</sup> Oxidation of benzoin by  $[\text{MoO}_2\text{L}_2]^{2-}$  ( $\text{L} = \text{bdt}$  derivatives) proceeds according to equation (19); a deuterium isotope effect (see *Isotope Effect*),  $k_{\text{H}}/k_{\text{D}} \sim 4.0$ , is consistent with  $\alpha$ -hydrogen atom abstraction by an oxo ligand in the rate-determining step.<sup>68</sup> Mo-MPT enzymes catalyze the conversion of  $\text{RCH}(\text{OH})\text{CO}_2^-$ , a substrate similar to benzoin, to  $\text{RCOCO}_2^-$ .

The reactions of  $[\text{MoOL}_2]^{2-}$  with  $\text{Me}_3\text{NO}$  to give  $[\text{MoO}_2\text{L}_2]^{2-}$  and  $\text{Me}_3\text{N}$  (cf. equation 11) are pseudo-first-order with  $k_{\text{obs}}$  values in the range  $2.6(5) \times 10^{-3}$  to  $5.7(4) \times 10^{-3} \text{ s}^{-1}$  for  $\text{L} = \text{bdt}$  derivatives.<sup>54</sup> The reactions are proposed to occur via binding of  $\text{Me}_3\text{NO}$  to the trans vacant site (see *Vacant Site*) of  $[\text{MoOL}_2]^{2-}$ , followed by a *trans*  $\rightarrow$  *cis* rearrangement and cleavage of the N–O bond. A dramatic rate enhancement (ca.  $10^4\text{--}10^5$ ) is observed for complexes stabilized by ligand  $\text{NH} \cdots \text{S}$ (dithiolene) hydrogen bond interactions.<sup>73</sup>

## 9.2 Structural and Functional Models

The synthesis and study of monooxo-Mo(VI) and desoxo-Mo(IV) bis(dithiolene) complexes are recent developments in this area; associated chemistry is summarized in Scheme 7. The oxo-Mo(VI) complexes,  $\text{NEt}_4[\text{MoO}(\text{OR})\text{L}_2]$ , are prepared by silylation of  $(\text{NEt}_4)_2[\text{MoO}_2\text{L}_2]$  with  $\text{ClSi}^i\text{BuPh}_2$  ( $\text{R} = \text{Si}^i\text{BuPh}_2$ ) or by OAT to the Mo(IV) complexes  $\text{NEt}_4[\text{Mo}(\text{OR})\text{L}_2]$  ( $\text{R} = i\text{Pr}, 2\text{-Ad}, \text{Ph}$  etc.;  $\text{L} = \text{bdt}, \text{S}_2\text{C}_2\text{R}'_2$  ( $\text{R}' = \text{H}, \text{Me}, \text{Ph}$ )).<sup>74</sup> Structurally characterized  $\text{NEt}_4[\text{MoO}(\text{OSi}^i\text{BuPh}_2)(\text{bdt})_2]$  (Figure 9) exhibits a severely distorted octahedral structure, with *cis* O-donors and  $d(\text{Mo}=\text{O})$  1.715(2) Å,  $d(\text{Mo}—\text{O})$  1.932(2) Å, and  $\angle(\text{Mo}—\text{O}—\text{C}) = 160.0(2)^\circ$ ; the Mo–S bond ‘trans’ to oxo is longer than the others present. Complexes containing authentic dithiolene ligands are unstable to hydrolysis but their W analogues have been isolated and structurally characterized.

The desoxo-Mo(IV) complexes,  $\text{NEt}_4[\text{Mo}(\text{OR})\text{L}_2]$ , can be prepared by several methods. These include the silylation of  $(\text{NEt}_4)_2[\text{MoOL}_2]$ <sup>74</sup> or the reaction of the synthetically versatile complexes,  $\text{Mo}(\text{CO})_2\text{L}_2$ , with aryloxide ( $\text{RO}^-$ ), then  $\text{NEt}_4^+$  salts.<sup>75</sup> Many of these compounds have been structurally

<sup>a</sup>Bisulfite,<sup>72</sup> phosphite,<sup>69</sup> and phosphine<sup>70</sup> reactions in  $\text{MeCN}/\text{H}_2\text{O}$  (1:1), DMF and  $\text{MeCN}$  respectively. <sup>b</sup>Measured at 298 K. <sup>c</sup> $\Delta H^\ddagger$  in  $\text{kcal mol}^{-1}$ . <sup>d</sup> $\Delta S^\ddagger$  in eu. <sup>e</sup> $k_2'/K_{\text{M}}$  from Michaelis–Menten kinetics performed in  $\text{MeCN}/\text{H}_2\text{O}$  (1:1) at 293 K. <sup>f</sup>Ratio of  $k$  values,  $k_{\text{Mo}}/k_{\text{W}}$ . <sup>g</sup>Value of relative  $\sigma$  donor capability,  $\chi$  ( $\text{cm}^{-1}$ ).

**Figure 9** Partial structure of the anion of  $\text{NEt}_4[\text{MoO}(\text{OSi}^t\text{BuPh}_2)\text{-(bdt)}_2]$  ( $^t\text{Bu}$  methyl groups excluded)

**Figure 10** Structure of the anion of  $\text{NEt}_4[\text{Mo}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]$

characterized and they all contain square-pyramidal anions with apical  $\text{RO}^-$  ( $d(\text{Mo}-\text{O})$  ca. 1.84 Å,  $\angle(\text{Mo}-\text{O}-\text{C}) > 166^\circ$ ), and basal S-donor ligands (see Figure 10);<sup>74–76</sup> they are prone to hydrolysis according to Scheme 7.<sup>76</sup> Various S-, N- and Se-oxides react with  $\text{NEt}_4[\text{Mo}(\text{OR})(\text{S}_2\text{C}_2\text{Ph}_2)_2]$  to produce  $\text{NEt}_4[\text{MoO}(\text{OR})(\text{S}_2\text{C}_2\text{Ph}_2)_2]$ , which subsequently converts to  $\text{NEt}_4[\text{MoO}(\text{S}_2\text{C}_2\text{Ph}_2)_2]$ . Kinetics and isotope labeling studies are consistent with initial OAT through associative mechanisms (Table 4).<sup>76</sup> The desoxo-W(IV) analogues are oxidized at significantly increased rates compared to the Mo complexes (Table 4).<sup>77</sup> Similar comparative rates are observed for Mo-MPT enzymes and their W analogues.<sup>55,71</sup> Theoretical studies have shown that the OAT reactions of  $[\text{Mo}(\text{OR})\text{L}_2]^-$  complexes are favored over those of  $[\text{MoOL}_2]^{2-}$  species by a lower-energy transition state and more stable products.<sup>78,79</sup> The Mo(VI) and Mo(IV) complexes above are excellent structural and functional models for the oxidized and reduced states of DMSO reductase. They also reproduce absorptions at similar wavelengths to those observed for the enzyme from *R. sphaeroides*. The desoxo-Mo(IV) complexes are reduced only at very negative potentials, a fact likely to account for the absence of Mo(III) enzyme states.

<sup>a</sup>Measured at 298 K. <sup>b</sup> $\Delta H^\ddagger$  in  $\text{kcal.mol}^{-1}$ . <sup>c</sup> $\Delta S^\ddagger$  in eu. <sup>d</sup>For analogous reactions of  $[\text{W}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  (units as above):  $\text{C}_4\text{H}_8\text{SO}$ ,  $k$   $9.0(3) \times 10^{-4}$ ,  $\Delta H^\ddagger$  11.6(4),  $\Delta S^\ddagger$  −33(1);  $\text{DMSO}$ ,  $k$   $3.9(4) \times 10^{-5}$ ,  $\Delta H^\ddagger$  14.4(2),  $\Delta S^\ddagger$  −30(1).<sup>77</sup>

Thiolates and selenolates react with  $\text{Mo}(\text{CO})_2(\text{S}_2\text{C}_2\text{Me}_2)_2$ , allowing the isolation of compounds of the type  $\text{NEt}_4[\text{Mo}(\text{ER})(\text{S}_2\text{C}_2\text{Me}_2)_2]$  ( $\text{E} = \text{S}$ ,  $\text{R} = \text{C}_6\text{H}_2^i\text{Pr}_3\text{-2,4,6}$ , 2-Ad;  $\text{E} = \text{Se}$ ,  $\text{R} = 2\text{-Ad}$ ).<sup>75,76</sup> Like the desoxo complexes above, these exhibit square-pyramidal structures, with apical  $\text{RE}^-$  groups and basal S-donor ligands. Interestingly, the  $\text{Mo}-\text{E}-\text{C}$  angles are considerably more bent (at ca.  $102^\circ$ ) than the corresponding angles in  $\text{RO}^-$  complexes. These compounds are valuable structural and spectroscopic models for the active sites of dissimilatory nitrate reductases ( $\text{E} = \text{S}$ ) and formate dehydrogenases ( $\text{E} = \text{Se}$ ). Analogous W complexes are known.

## 10 MODELS FOR THE SULFITE OXIDASE FAMILY

### 10.1 Structural and Spectroscopic Models

Holm and coworkers have very recently described advanced structural models for the Mo(VI) and Mo(V) states of sulfite oxidase. Thus, the reaction sequence shown in Scheme 8 yields dioxo mono(dithiolene) complexes bearing either silyloxo or thiolate ligands. The thiolate complex,  $[\text{MoO}_2(\text{SC}_6\text{H}_2^i\text{Pr}_3\text{-2,4,6})(\text{bdt})]^-$ , exhibits a square-pyramidal (pseudotetrahedral) structure closely related to that of oxidized sulfite oxidase (Figure 11).

The reaction represented by equation (20) is key to the generation of mono(dithiolene)-Mo(V) complexes that

**Scheme 8**

**Figure 11** Partial structure of the anion of  $\text{NEt}_4[\text{MoO}_2(\text{SC}_6\text{H}_2^i\text{Pr}_3-2,4,6)(\text{bdt})] \cdot \text{MeCN}$  ( $^i\text{Pr}$  groups not shown)

model the intermediate states of sulfite oxidase. Thereafter, chloride ligand exchange yields thiolate complexes such as  $[\text{MoO}(\text{SAd})_2(\text{S}_2\text{C}_2\text{Me}_2)]^-$ ,  $[\text{MoO}(\text{SR})_2(\text{bdt})]^-$ , and  $[\text{MoOCl}(\text{SC}_6\text{H}_2^i\text{Pr}_3-2,4,6)(\text{bdt})]^-$ . These exhibit square-pyramidal geometries with apical oxo groups and rhombic EPR spectra similar to the low-pH and high-pH forms of sulfite oxidase (Figure 4).<sup>80</sup>

The energy and profile of the X-ray absorption edges of the above mono(dithiolene) complexes are sensitive to the oxidation state and ligands present. In particular, the Mo K-edge XAS and EXAFS spectra of  $\text{NEt}_4[\text{MoO}_2(\text{SC}_6\text{H}_2^i\text{Pr}_3-2,4,6)(\text{bdt})]$  are remarkably similar to the corresponding spectra of oxidized sulfite oxidase. Further developments in this area, including biomimetic chemistry, are eagerly anticipated.

The most recent oxo-Mo(V) models for sulfite oxidase include  $(\text{L}-\text{N}_2\text{S})\text{MoO}(\text{SPh})_2$  and  $(\text{L}-\text{N}_2\text{S})\text{MoO}(\text{bdt})$ , prepared by thiolate ligand exchange at  $[\text{MoO}(\text{SPh})_4]^-$ , then  $(\text{L}-\text{N}_2\text{S})\text{MoO}(\text{SPh})_2$ , respectively ( $\text{L}-\text{NS}_2$  = anion of (2-dimethylethanethiol)bis(3,5-dimethylpyrazolyl)methane). Both complexes exhibit distorted octahedral structures and *facial*  $\text{L}-\text{N}_2\text{S}$  ligands and have been characterized by electronic and EPR spectroscopy.<sup>81</sup>

## 10.2 Functional Models

Functional models for sulfite oxidase are extremely uncommon. A well-studied example is the reaction of  $(\text{NBu}_4)_2[\text{MoO}_2(\text{mnt})_2]$  with  $\text{NaHSO}_3$  in acetonitrile/water mixtures, which proceeds smoothly according to equation (21). However, the mechanism of this ‘simple’ reaction remains controversial.<sup>54</sup>

The reaction exhibits substrate saturation kinetics, consistent with a pre-equilibrium between  $[\text{MoO}_2(\text{mnt})_2]^{2-}$  and

$\text{HSO}_3^-$ , rather than the substrate first-order dependence typical of direct OAT reactions (Section 7.3). Originally, Sarkar and coworkers proposed that  $\text{HSO}_3^-$  binds to Mo via its anionic oxygen, prior to nucleophilic attack by sulfur at an oxo group of putative  $[\text{Mo}^{\text{VI}}\text{O}_2(\text{HSO}_3)(\text{mnt})_2]^{3-}$ , giving bound  $\text{HSO}_4^-$ , that then dissociates.<sup>72</sup> This mechanism was later challenged by Lorber *et al.*,<sup>70</sup> who suggested the direct nucleophilic attack by the sulfur lone pair on a terminal oxo ligand, giving  $[\text{Mo}^{\text{IV}}\text{O}(\text{HSO}_4)(\text{mnt})_2]^{3-}$ , followed by product dissociation. The recent observation that neutral dimethylsulfite fails to react with  $[\text{MoO}_2(\text{mnt})_2]^{2-}$  supports the mechanism involving oxoanion coordination to Mo prior to OAT.<sup>82</sup> Similar uncertainties surround the mechanism of the enzyme itself (Section 5). The oxidation of  $[\text{MoO}(\text{mnt})_2]^{2-}$  using  $[\text{Fe}(\text{CN})_6]^{3-}/\text{H}_2\text{O}$  results in partial reclamation (ca 10%) of  $[\text{MoO}_2(\text{mnt})_2]^{2-}$ , possibly via CEPT reactions mimicking the regeneration of the active site of sulfite oxidase.<sup>54</sup> The reduction of nitrate by several oxo-Mo(IV) complexes has been described.<sup>54</sup>

## 11 MODELS FOR THE XANTHINE OXIDASE FAMILY

### 11.1 Models of the Oxidized Active Enzyme

The Mo hydroxylases are difficult to model because of the general redox incompatibility of the reducing sulfide and oxidizing Mo(VI) moieties found in the enzymes. The outcomes and directions of modeling endeavors up to 1997 have been reviewed by Young.<sup>61</sup>

Pseudotetrahedral complexes, such as  $[\text{MoO}_{4-n}\text{S}_n]^{2-}$  ( $n = 1-3$ ),  $\text{MoOS}(\text{ONR}_2)_2$  and  $\text{Cp}^*\text{MoOS}(\text{CH}_2\text{SiMe}_3)_3$ , are well known; their stability may be ascribed to the low effective coordination number and consequently large HOMO-LUMO gap (*see HOMO-LUMO Gap*). Compounds of this type are prepared by sulfidation (oxo  $\rightarrow$  sulfido) reactions but decomposition, upon reduction or attempted biomimetic transformations (e.g. cyanolysis), limits their biomimetic chemistry.<sup>61</sup> The first six-coordinate oxosulfido-Mo(VI) complex,  $\text{Tp}^*\text{MoOS}(\text{S}_2\text{P}^i\text{Pr}_2)_2$ , was prepared by sulfur atom transfer to the Mo(IV) precursor,  $\text{Tp}^*\text{MoO}(\text{S}_2\text{P}^i\text{Pr}_2)_2$ . Metrical parameters were consistent with an oxosulfido-Mo(VI) formulation, the ‘terminal’ sulfido ligand being stabilized by a weak interaction with the uncoordinated sulfur of the monodentate dithiophosphinate ligand; regardless, the complex is cleanly reduced to an oxosulfido-Mo(V) species and undergoes cyanolysis/sulfidation reactions that mimic those of the hydroxylases.<sup>83</sup> The complexes,  $\text{MoOS}(\text{OSiPh}_3)_2\text{L}$  (L = bpy or phen derivative), prepared by reaction of  $\text{K}_2[\text{MoO}_3\text{S}]$ ,  $\text{ClSiPh}_3$ , and L in basic ( $\text{NEt}_3$ ) acetonitrile, contain an unperturbed oxosulfido unit. The structures of the complexes were defined by X-ray diffraction and EXAFS spectroscopy ( $d(\text{Mo}=\text{O})$  ca. 1.71 Å,  $d(\text{Mo}=\text{S})$  ca. 2.18 Å).<sup>84</sup> Exploitation of

the sterically demanding  $\text{Tp}^{\text{Pr}}$  ligand has now permitted the synthesis of a series of oxosulfido-Mo(VI) complexes of the type  $\text{Tp}^{\text{Pr}}\text{MoOS}(\text{OR})$  ( $\text{OR}$  = phenolate derivative). The parent complex,  $\text{Tp}^{\text{Pr}}\text{MoOS}(\text{OPh})$ , is monomeric in solution but crystallizes as a dimer, the two units being linked by a S–S bond formed with concomitant reduction of Mo(VI) to Mo(V).<sup>85</sup> Complexes that are monomeric in both the solution and solid states have now been isolated and structurally characterized (Figure 12); these are amenable to a reversible reduction producing Mo(V) species (vide infra). Oxosulfido-Mo(VI) complexes undergo sulfur rather than oxygen atom transfer to phosphines and cyanide.<sup>83–85</sup> This observation argues against enzyme mechanisms postulating direct involvement of the terminal oxo group in OAT.

## 11.2 Models of Mo(V) States

Oxosulfido-Mo(V) complexes are relevant models of the Very Rapid Mo(V) enzyme center but these too are extremely rare. The in situ generation and EPR characterization of complexes such as  $[(\text{L}-\text{N}_2\text{S}_2)\text{Mo}^{\text{V}}\text{OS}]^-$  and  $[\text{Tp}^*\text{Mo}^{\text{V}}\text{OSX}]^-$  was summarized in *EIC-1*.<sup>1</sup> Identification of  $[(\text{L}-\text{N}_2\text{S}_2)\text{Mo}^{\text{V}}\text{OS}]^-$  rests upon multifrequency EPR studies employing complexes isotopically labelled with  $^{98}\text{Mo}$  ( $I = 0$ ),  $^{33}\text{S}$  ( $I = 3/2$ ), and/or  $^1\text{H}$  ( $I = 1/2$ ). In particular, the distinctive pattern of anisotropic  $^{33}\text{S}$  coupling (dominated by a single direction) observed in the Very Rapid signal of xanthine oxidase is reproduced so convincingly by  $[(\text{L}-\text{N}_2\text{S}_2)^{98}\text{MoO}^{33}\text{S}]^-$  that there can be little doubt that an  $[\text{Mo}^{\text{V}}\text{OS}]^+$  center (Figure 6) is responsible for the enzyme signal. In addition, the Mo-sulfido interaction is highly delocalized with a spin density of 0.3–0.4 of an electron on the sulfido ligand. The EPR parameters of

**Figure 12** Structure of  $\text{Tp}^{\text{Pr}}\text{MoOS}(\text{OC}_6\text{H}_4^s\text{Bu-2})$

**Figure 13** Structure of  $\text{CoCp}_2[\text{Tp}^{\text{Pr}}\text{MoOS}(\text{OPh})]$

natural abundance  $[\text{Tp}^*\text{Mo}^{\text{V}}\text{OSX}]^-$  are very similar to those of  $[(\text{L}-\text{N}_2\text{S}_2)\text{Mo}^{\text{V}}\text{OS}]^-$ .<sup>53</sup>

Protonation of the synthetic species to  $\text{cis}-[\text{MoO}^{\text{V}}(\text{SH})]^{2+}$  collapses both the magnitude and the anisotropy of the  $^{33}\text{S}$  coupling in addition to inducing the appearance of  $^1\text{H}$  coupling.<sup>1,53</sup> These features are characteristic of the centers responsible for the Rapid EPR signals (Figure 6). The delocalized nature of the Mo–S bond in  $\text{cis}-[\text{Mo}^{\text{V}}\text{OS}]^+$  has been rationalized in terms of a highly covalent  $\text{Mo}(d_{xy})-\text{S}(p_y)$  interaction perpendicular to the strong-field oxo ligand ( $z$ ). Claims that  $(\text{L}-\text{N}_2\text{S}_2)\text{Mo}^{\text{V}}\text{O}(\text{SH})$  and salts of  $[(\text{L}-\text{N}_2\text{S}_2)\text{Mo}^{\text{V}}\text{OS}]^-$  have been isolated are doubtful. In contrast, salts such as  $\text{CoCp}_2[\text{Tp}^{\text{Pr}}\text{MoOS}(\text{OR})]$  ( $\text{OR}$  = phenolate derivative) are tractable and a preliminary (O/S disordered) X-ray crystal structure of  $\text{CoCp}_2[\text{Tp}^{\text{Pr}}\text{MoOS}(\text{OPh})]$  has been achieved (see Figure 13). EXAFS results are indicative of  $\text{Mo}=\text{O}$  and  $\text{Mo}=\text{S}$  distances of 1.72 Å and 2.23 Å respectively, while a strong S K pre-edge XAS feature is associated with the  $\pi$ -bonded sulfido group.

## 12 CONCLUSION

The Mo-MPT enzymes play vital roles in metabolism and global biogeochemical cycles, their myriad functions being facilitated by the chemical versatility of Mo on one hand and the substrate specificity induced by the structure of the active site and the protein on the other. In recent years, our knowledge of these enzymes has increased dramatically, thanks to insights from advanced structural, spectroscopic, and molecular biological techniques. The intrinsic OAT and CEPT capabilities of Mo appear to be central to the function of many enzymes but complete mechanistic descriptions await the results of ongoing investigations. Model studies have made vital contributions to our appreciation of the enzyme active sites and accurate active-site models are now emerging.

Exploration of the structure and function of Mo-MPT enzymes, from (inter alia) molecular, cellular, environmental, and evolutionary perspectives, promises to fully inform our knowledge of these important and interesting biomolecules.

## 1 INTRODUCTION

Molybdenum is a transition metal that is found in group 6 of the periodic table and has a ground-state electronic configuration of  $4d^5 5s^1$ . It has a crustal abundance of  $\sim 1.2$  ppm. The most important molybdenum ore is molybdenite,  $\text{MoS}_2$ , with the largest known deposit in Colorado, USA. Other less important ores include wulfenite,  $\text{PbMoO}_4$ , and powellite,  $\text{Ca}(\text{Mo}, \text{W})\text{O}_4$ . It was first isolated by P. J. Hjelm in the late eighteenth century by heating the oxide  $\text{MoO}_2$  with charcoal. The name molybdenum is derived from the Greek word for lead ( $\mu\omicron\lambda\nu\beta\delta\omicron\varsigma$ , molybdos). This naming arose because of the ancient confusion of soft black minerals that were used for writing. It has an atomic number 42, atomic weight 95.94, mp  $2617^\circ\text{C}$ , and bp  $4612^\circ\text{C}$ . Molybdenum has found extensive use in the steel industry where it is used in high temperature cutting steel, its compounds find use as lubricants, for example,  $\text{MoS}_2$ , as pigments and catalysts.

Since this article is concerned with molybdenum organometallic chemistry and owing to the immense number of publications each year in this area of science, the author has had to be selective in the areas that are covered. For compounds to be given initial consideration for inclusion, they have to contain a direct molybdenum-to-carbon bond. This article is organized on the basis of the type of carbon-based ligand and the number of atoms directly bound to the molybdenum center. Where there are two or more carbon-based ligands in the compound, the compound is placed in the section perceived to be most relevant. The reader will find that some areas were covered in the Encyclopedia of Inorganic Chemistry, First Edition,<sup>1</sup> and others are new to this edition. The two articles are therefore complimentary. The same referencing policy is used in this article as in the previous edition.

Citations are made to review articles wherever possible and where none are available to lead references.

## 2 $\sigma$ -LIGAND-CONTAINING COMPLEXES

### 2.1 Alkyl Complexes

#### 2.1.1 Homoleptic Complexes

In 1973, Wilkinson reported the preparation of the homoleptic methyl compounds (*see Homoleptic Compound*)  $[\text{W}(\text{CH}_3)_6]$  and  $[\text{Re}(\text{CH}_3)_6]$ . Later, theoretical calculations suggested that these compounds should be based upon trigonal prismatic geometry rather than octahedral as is common in six-coordinate coordination chemistry, and the structure of  $[\text{W}(\text{CH}_3)_6]$  was subsequently shown to be strongly distorted  $\text{C}_{3v}$  trigonal prismatic.<sup>2</sup> The structure is of particular interest because it contains three long W–C bonds at a narrow angle to each other and three shorter W–C bonds at a larger angle. Recently, the compounds  $[\text{Mo}(\text{CH}_3)_5]$ ,  $[\text{Mo}(\text{CH}_3)_6]$ , and  $[\text{Mo}(\text{CH}_3)_7]$  have been prepared and structurally characterized.<sup>3,4</sup> Blue  $[\text{Mo}(\text{CH}_3)_5]$  is prepared through reaction of  $\text{MoCl}_5$  with  $\text{ZnMe}_2$ . The compound is paramagnetic and has a square pyramidal geometry with Mo–C<sub>apical</sub> 2.068(1) Å and Mo–C<sub>basal</sub> 2.111(1) Å. Orange–brown  $[\text{Mo}(\text{CH}_3)_6]$  is prepared on treatment of  $\text{MoF}_6$  with  $\text{Zn}(\text{CH}_3)_2$  and is thermally stable up to  $10^\circ\text{C}$  and very sensitive toward oxygen. Its solid-state structure is similar to its tungsten analog. The structure is strongly distorted trigonal prismatic with three short Mo–C bonds 2.111(3) Å with C–Mo–C  $94.9^\circ$  and three long Mo–C bonds 2.190(3) Å with C–Mo–C  $75.7^\circ$ . Red  $[\text{Li}\{\text{O}(\text{CH}_2\text{CH}_3)_2\}][\text{Mo}(\text{CH}_3)_7]$  was prepared on treatment of  $[\text{Mo}(\text{CH}_3)_6]$  with MeLi and is isostructural with its tungsten analog  $[\text{Li}\{\text{O}(\text{CH}_2\text{CH}_3)_2\}][\text{W}(\text{CH}_3)_7]$ . The structure is best described as a capped octahedron. In none of the reported structures was there any evidence for an agostic interaction (*see Agostic Bonding*), and the relative stability of all these compounds stems from the fact that the methyl group does not contain any  $\beta$ -hydrogen atoms.

#### 2.1.2 Nonhomoleptic Complexes

Alkyl-, aryl-, and acetylide-containing compounds that have additional ligands such as phosphines and cyclopentadienyl, amongst others, are far more common than their homoleptic congeners. Examples of this type of compound will be found in other sections of the article.

## 2.2 Carbonyl Derivatives

### 2.2.1 Mononuclear Complexes

The starting point for most molybdenum-based carbonyl chemistry is the white crystalline air stable hexacarbonyl  $[\text{Mo}(\text{CO})_6]$ , which is commercially available. Low valent compounds that are derived from this starting material tend to give products that obey the Effective Atomic Number Rule (EAN Rule). Since  $\text{Mo}^0$  has a  $d^6$  configuration, six two-electron ligands are required to obey the EAN rule.

**Bonding Considerations.**  $[\text{Mo}(\text{CO})_6]$  is stabilized by back bonding of electrons from the  $d_\pi$  orbitals ( $d_{xy}$ ,  $d_{xz}$ ,  $d_{yz}$ ) into the  $\pi^*$ -molecular orbitals of the carbon monoxide ligands (see **Molecular Orbital Theory**). This back donation of electrons serves to lower the negative charge at the molybdenum center and so strengthens the  $\sigma$ -donation (see **S-donor Ligands**) from the ligand to the molybdenum atom. The compound  $[\text{Mo}(\text{CO})_6]$  has strict  $O_h$  symmetry (see **Group Theory**) and all six d-electrons are involved in back donation to the  $\pi^*$ -molecular orbitals of the carbonyl ligands. This results in three identical pairs of *trans*-carbonyl ligands that each competes with each other for the available electron density (see Figure 1a). When the first carbonyl is substituted by another two-electron donor ligand that is a poorer  $\pi$ -acceptor (this will generally be the case), then the carbonyl ligand *trans* to this ligand will obtain a greater share of the electron density with the overall result that the  $\text{Mo}-\text{CO}$  bond *trans* to the ligand L is strengthened relative to the *cis* carbonyl ligands (see Figure 1b). The outcome of this strengthening of the bond is that on substitution of a second carbonyl ligand *cis*- $[\text{Mo}(\text{CO})_4\text{L}_2]$  and a third *fac*- $[\text{Mo}(\text{CO})_3\text{L}_3]$  respectively are obtained. Facile substitution ceases at this point because all of the remaining carbonyl ligands are *trans* (generally) to poorer  $\pi$ -acceptor ligands. Further substitution can be facilitated under more forcing conditions or through the use of chelating ligands (see **Chelating Ligands**) and/or good  $\pi$ -acceptors (see **Carbonyl Complexes of the Transition Metals**).

In  $[\text{Mo}(\text{CO})_6]$ , the  $\text{Mo}-\text{CO}$  bond length is 2.06 Å and the average  $\text{Mo}-\text{CO}$  bond energy (see **Bonding Energetics of Organometallic Compounds**) is 150 kJ mol<sup>-1</sup>.

**Figure 1** (a) Portion of a molecular orbital that distributes electron density between two *trans*-carbonyl groups. (b) electron density concentrated in  $\text{M}-\text{CO}$  bond *trans* to poor  $\pi$ -acceptor

**Spectral Characteristics.** IR spectra (*Infrared Spectroscopy*) are particularly useful for making gross structural assignments in mononuclear carbonyl derivatives.  $[\text{Mo}(\text{CO})_6]$  is octahedral and has a single carbonyl stretching frequency at 2004 cm<sup>-1</sup>. The  $\delta-\text{M}-\text{C}-\text{O}$  bending mode appears at 593 cm<sup>-1</sup> and the  $\text{M}-\text{C}$  stretch ( $t_{1u}$ ) occurs at 368 cm<sup>-1</sup>. Substitution of one carbonyl ligand lowers the effective symmetry to  $C_{4v}$  (see **Group Theory**), and three  $\nu(\text{CO})$  bands become IR active ( $2a + e$ ) in the 2050 to 1850 cm<sup>-1</sup> range. *cis*- $[\text{Mo}(\text{CO})_4\text{L}_2]$  has effective  $C_{2v}$  symmetry, and four  $\nu(\text{CO})$  modes ( $2a_1 + b_1 + b_2$ ) are active. *trans*- $[\text{Mo}(\text{CO})_4\text{LL}']$  has either  $D_{4h}$  ( $L = L'$ ) or  $C_{4v}$  ( $L \neq L'$ ) symmetry, with one ( $e_u$ ) or two ( $a_1(\text{weak}) + e$ )  $\nu(\text{CO})$  bands respectively. *Tri*-substituted *fac*- $[\text{Mo}(\text{CO})_3\text{L}_3]$  has  $C_{3v}$  symmetry with two ( $a_1 + e$ )  $\nu(\text{CO})$  bands. The average  $\nu(\text{CO})$  frequency decreases with increasing substitution.<sup>5</sup>

In <sup>13</sup>C NMR spectra, the carbonyl carbon resonance appears typically in the 200–230 ppm region. If the compound contains phosphine ligands, then the carbonyl signals couple with the spin active phosphorus atom and can be used to complement geometry assignment made using IR spectroscopy. <sup>1</sup>H NMR is also useful for characterizing these compounds due to the signals of the organic moieties in the ligands. Typically, the signals are slightly shifted from those observed for the noncomplexed ligand.<sup>6</sup>

### 2.2.2 Reductive Substitution

Molybdenum carbonyls react with strong reducing agents to give carbonyl metallates in which the molybdenum is formally reduced.<sup>7</sup> Thus,  $[\text{Mo}(\text{CO})_6]$  or  $[\text{Mo}(\text{CO})_5\text{L}]$  reacts with strong reducing agents in liquid ammonia or THF to form  $[\text{Mo}(\text{CO})_5]^{2-}$  and  $[\text{Mo}_2(\text{CO})_{10}]^{2-}$  respectively. The dimeric dianion is best obtained with sodium in the presence of a catalytic amount of bipyridine or from  $\text{NaBH}_4$  at 60 °C in ammonia.  $[\text{Mo}(\text{CO})_5]^{2-}$  is best prepared from the dimer on treatment with CO (equation 1). The  $[\text{Mo}(\text{CO})_6]$  obtained as a side product is readily removed by sublimation.

Reduction of  $[\text{Mo}(\text{CO})_4(\text{TMEDA})]$  with sodium in liquid ammonia affords excellent yields of  $\text{Na}_4[\text{Mo}(\text{CO})_4]^{4-}$ , which can be isolated as a pyrophoric yellow–orange powder. In this compound, molybdenum shows its lowest formal oxidation state as evidenced by the very low value of  $\nu(\text{CO})$  1471 cm<sup>-1</sup>.

These carbonyl anions are strong nucleophiles (see **Nucleophile**) and can be used to form a diverse range of new compounds. Protonation gives the  $\mu$ -hydride (see **Bridging Ligand**)  $[(\mu-\text{H})\{\text{Mo}(\text{CO})_5\}]$ . Reactions with other metal carbonyls lead to CO substitution and the formation of metal–metal-bonded heteronuclear anions, for example,  $[\text{Mo}(\text{CO})_5-\text{Fe}(\text{CO})_4]^{2-}$  and  $[\text{Mo}(\text{CO})_5-\text{Co}(\text{CO})_4]^{2-}$ . Reaction with main group halides is shown in Scheme 1. The dianion reacts similarly.

**Scheme 1** Selected reactions of  $[\text{Mo}(\text{CO})_5]^{2-}$

**Scheme 2** Preparation of Fischer carbene complexes

## 2.3 Carbene and Carbyne Complexes

The carbon atom of the carbonyl ligand in  $[\text{Mo}(\text{CO})_6]$  or its derivatives may be attacked by strong nucleophiles (see *Nucleophile*) like organo-lithium reagents. The resulting anion from this nucleophilic attack can be quenched with an electrophilic reagent (see *Electrophile*), for example, trialkyloxonium methylfluorosulfonates (Scheme 2). The resultant neutral species are known as carbene complexes (see *Carbene Complexes*) or Fischer-type carbene complexes.<sup>8</sup> The related Cr and W analogs and to a lesser extent the Mo analogs have found utility as reagents in organic syntheses (see *Organic Synthesis using Transition Metal Carbonyl Complexes*) and as catalysts for alkene metathesis (see *Metathesis Polymerization Processes by Homogeneous Catalysis*). Alternative routes to Mo-carbene complexes include the treatment of  $[\text{Mo}(\text{CO})_6]$  with electron-rich alkenes and reaction of the carbonylate anion  $[\text{Mo}(\text{CO})_5]^{2-}$  with various substrates such as 3,3-dichlorocyclopropenes or iminium salts.<sup>9</sup>

These Fischer-type carbene complexes can be readily converted to Fischer-type carbyne complexes, and this material has been reviewed.<sup>10</sup> Methods to remove the  $\alpha$ -alkoxy group include treatment with  $\text{BBr}_3$ , oxide abstraction from acyl ligands, and electrophilic attack on the  $\beta$ -carbon of

metal acetylides (equations 2–4).

### 2.3.1 Heavier Group 14 Analogs of Carbene and Carbyne Complexes

Multiple bonds are readily formed with the 2p elements carbon, nitrogen, and oxygen; however, the heavier main group elements only reluctantly participate in multiple bonding<sup>11</sup> (see *Main Group: Multiple Bonding*) since the mid-1960s, considerable effort has been expended to generate heavier group 14 analogs and investigate their coordination chemistry. Some dated reviews are available.<sup>12,13</sup> On complexation of the divalent group 14 element moiety (Figure 2a), it retains its Lewis acid characteristics and often coordinates a Lewis base (Figure 2b), and there are even examples of the coordination of two Lewis bases (Figure 2c) (see *Lewis Acids & Bases*). The reversal of this process to generate the base-free species has always failed and results in compound decomposition. More recently, attempts to prepare heavier group 14 analogs of carbyne complexes have resulted in the preparation of silylyne- and germylyne-containing molybdenum complexes and a stannylyne-containing complex of tungsten.

**Silicon.** The first base-stabilized silylene complex  $[\text{Cp}^*\text{Ru}=\text{Si}(\text{Ph})_2\text{NCMe}](\text{PMe}_3)_2]$  was reported in 1987, and the first base-free silylene-containing complexes  $[\text{Cp}^*\text{Ru}=\text{Si}(\text{SR})_2(\text{PMe}_3)_2]$  ( $\text{R} = \text{Me}$  or  $\text{Ph}$ ) were not synthesized until 1990, much later than for the heavier congeners Ge, Sn, and Pb. Recently, the silylene-containing

**Figure 2** Representation of different classes of double-bonded group 14 fragments

compound  $[\text{Cp}^*\text{Mo}=\text{SiCl}(\text{C}_6\text{H}_2\text{-2,4,6-Me}_3)\text{H}(\text{dmpe})]$  (**1**) has been prepared<sup>14</sup> and structurally characterized. In this compound, the sum of the angles about the silicon atom is  $359.8(3)^\circ$ , which is indicative of a base-free silylene complex that is  $\text{sp}^2$  hybridized (see *Hybridization*) at the silicon center. The Mo–Si bond length is short ( $2.288(2) \text{ \AA}$ ), which confirms its multiple bond character. Compound (**1**) was then treated with  $\text{Li}[\text{B}(\text{C}_6\text{F}_5)_4]$  to facilitate chloride abstraction and generation of the cationic silylyne-containing complex  $[\text{Cp}^*\text{Mo}\equiv\text{Si}(\text{C}_6\text{H}_2\text{-2,4,6-Me}_3)\text{H}(\text{dmpe})][\text{B}(\text{C}_6\text{F}_5)_4]$  (**2**), which has also been structurally characterized. In the solid-state structure of (**2**), the Mo–Si bond length shortened to  $2.219(2) \text{ \AA}$  and the Mo–Si–C angle is  $170.9(2)^\circ$  and is comparable to analogous carbyne-containing compounds.<sup>10</sup>

Another interesting feature in the solid-state structure of (**2**) is the presence of a bridging hydride (see *Bridging Ligand*): Mo–H  $1.85(5) \text{ \AA}$ , Si–H  $1.39(5) \text{ \AA}$ , although in heavy metal structures it is often difficult to make too much comment on the location of a hydrogen atom this close to a metal center (see *Diffraction Methods in Inorganic Chemistry*). Density Functional Theory (DTF) (see *Density Functional Theory*) calculations were carried out and suggest the presence of a nonclassical bridging hydride (see *Bridging Ligand*) and support the position of the hydrogen atom observed in the solid-state structure.

**Germanium.** The compounds  $[\text{Mo}(\text{CO})_5(\text{GeX}_2\cdot\text{THF})]$  ( $\text{X} = \text{Cl}, \text{Br}$ ) were prepared on treatment of the decacarbonyldimolybdate dianion with  $\text{GeX}_4$  in THF.<sup>12</sup> They were, however, originally erroneously reported as base-free species. Many more examples of this type of germylene-containing complex have been prepared where the central metal is Cr or W. Recently, the *tris*-carbene-containing molybdenum (0) complex  $[\text{Mo}(\text{Ge}\{\text{N}(\text{CH}_2^t\text{Bu})\text{C}_2\text{H}_2\text{N}(\text{CH}_2^t\text{Bu})\})_3(\text{CO})_3]$  was synthesized and structurally characterized. The average Mo–Ge bond length is  $2.537(2) \text{ \AA}$ , which is shorter than the sum of the covalent radii.<sup>15</sup> Lengthening of the Ge–N bond lengths and shortening of other bond lengths in the cyclic germylene ligand suggest that it is a good  $\pi$ -acceptor (see *Bond Lengths in Inorganic Solids & Liquids*).

Compounds that contain a germylyne ligand, that is, a metal–germanium triple bond have also been synthesized. Treatment of  $\text{Na}[\text{CpMo}(\text{CO})_3]$  with 2,6-Mes<sub>2</sub>C<sub>6</sub>H<sub>3</sub>GeCl at low temperature in THF afforded the germylyne-containing complex  $[\text{Cp}(\text{CO})_2\text{Mo}\equiv\text{GeC}_6\text{H}_3\text{-2,6-Mes}_2]$  (**3**), which has been structurally characterized.<sup>16</sup> The Mo–Ge–C angle of

$172.2(2)^\circ$  is similar to what is observed in carbyne-containing complexes and the related silylyne complex (**2**). The Mo–Ge bond length in (**3**) ( $2.271(1) \text{ \AA}$ ) is significantly shorter ( $0.35 \text{ \AA}$ ) than the predicted single bond length of  $2.62 \text{ \AA}$  (covalent radii Mo  $1.4 \text{ \AA}$  and Ge  $1.22 \text{ \AA}$ ). Unlike in the structure of (**2**), there are no close intramolecular approaches. Another synthetic strategy has also been described<sup>17</sup> for the preparation of the germylyne-containing compounds  $[(\text{dppe})\text{XMo}\equiv\text{Ge}(\eta^1\text{-Cp}^*)]$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) (equation 5). The compound  $[(\text{dppe})\text{BrMo}\equiv\text{Ge}(\eta^1\text{-Cp}^*)]$  has also been structurally characterized and found to have a linear Mo–Ge–C geometry  $171.6(2)^\circ$  and a short Mo–Ge bond length  $2.310(1) \text{ \AA}$ , which are comparable to those observed for (**3**).

Analogous Cr and W compounds have been prepared by the same methodology; however, in certain cases the tricarbonyl intermediates  $[\text{Cp}(\text{CO})_2\text{M}(\text{GeC}_6\text{H}_3\text{-2,6-Trip}_2)]$  ( $\text{M} = \text{Cr}$  **4**, **W** **5**;  $\text{Trip} = -\text{C}_6\text{H}_2\text{-2,4,6-}^i\text{Pr}_3$ ) that contain a M–Ge single bond were isolated. Both compounds have been structurally characterized and shown to have a stereochemically active lone pair at germanium and a bent M–Ge–C =  $117.9(3)^\circ$  (Cr)  $114.7(6)^\circ$  (W) geometry. Gentle heating of these compounds caused elimination of one carbonyl ligand and the formation of the triply bonded species  $[\text{Cp}(\text{CO})\text{M}\equiv\text{GeC}_6\text{H}_3\text{-2,6-Trip}_2]$  ( $\text{M} = \text{Cr}$  **6**, **W** **7**). Compounds (**6**) and (**7**) have both been structurally characterized and shown to have linear M–Ge–C geometry ( $175.9(6)^\circ$  Cr;  $170.9(3)^\circ$  W) and significantly shorter M–Ge bond lengths ( $2.166(4) \text{ \AA}$  Cr;  $2.277(1) \text{ \AA}$  W respectively).

**Tin and Lead.** A small number of molybdenum complexes containing stannylene and plumbylene ligands are known.<sup>12,13</sup> The tin and lead compounds  $[\text{Cp}(\text{CO})_3\text{Mo-EC}_6\text{H}_3\text{-2,6-Mes}_2]$  ( $\text{E} = \text{Sn}, \text{Pb}$ ) have been prepared but do not appear to lose CO and generate the stannylyne<sup>18</sup> or plumbylyne analogs of (**3**).<sup>19</sup> Very recently, however, the preparation of the tungsten complex  $[\text{W}\equiv\text{Sn}(\text{C}_6\text{H}_3\text{-2,6-Mes})\text{Cl}(\text{dppe})_2]$ , that does contain a stannylyne ligand, has been described.<sup>20</sup>

## 2.4 Halocarbonyl Complexes

### 2.4.1 Six- and Seven-Coordinate Complexes<sup>21,22</sup>

Halocarbonyl complexes of molybdenum have been known since Wilkinson and Piper reported the preparation of  $[\text{MoX}(\text{CO})_3\text{Cp}]$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) in 1956 with the first dihalocarbonyl donor ligand complex  $[\text{MoI}_2(\text{CO})_3(\text{diars})]$  reported by Nyholm and Nigram in 1957. Pioneering work by Colten in the 1960s led to the development of the halide-bridged dimers  $[\{\text{Mo}(\mu\text{-X})\text{X}(\text{CO})_4\}_2]$  via an oxidative elimination reaction between the halogen and  $[\text{Mo}(\text{CO})_6]$ . In

general, seven-coordinate halocarbonyl complexes have been shown to have one of the following structures: (i) capped octahedral, (ii) capped trigonal prismatic, (iii) pentagonal bipyramidal, (iv) or the so-called 4:3 geometry. Indeed,  $^{13}\text{C}$  NMR spectroscopy has been used to correlate the solid-state structures with solution state structures. In the case of capped octahedral structures, there is a shift to low field for the carbonyl in the capping position. Because these compounds are generally fluxional in solution (*see Stability Constants & their Determination*), to observe the capping carbonyl resonance the spectrum needs to be run at low temperature.

An early method for the preparation of a range of six- and seven-coordinate halocarbonyl complexes was the addition of soft donor ligands (*see Hard & Soft Acids and Bases*) to the halide-bridged dimer  $[\{\text{Mo}(\mu\text{-X})\text{X}(\text{CO})_4\}_2]$  to give  $[\text{MoX}_2(\text{CO})_3\text{L}_2]$ ; however, addition of weaker field ligands led to disproportionation and isolation of the non-carbonyl-containing compounds  $[\text{MoX}_3\text{L}_3]$  ( $\text{L} = \text{py}$ , THF, NCMe). An equally effective alternative to this method of preparation was oxidative elimination of the halogen to zero-valent molybdenum precursors such as  $[\text{Mo}(\text{CO})_4(\text{bpy})]$  to give  $[\text{MoX}_2(\text{CO})_3(\text{bpy})]$  ( $\text{X} = \text{Cl}$ , Br). The synthesis of the seven-coordinate halocarbonyl complexes  $[\text{MI}_2(\text{CO})_3(\text{NCMe})_2]$  ( $\text{M} = \text{Mo}$ , W) through the oxidative elimination of  $\text{I}_2$  to  $[\text{M}(\text{CO})_3(\text{NCMe})_3]$  ( $\text{M} = \text{Mo}$  or W) dissolved in acetonitrile has been described.<sup>23</sup> This is a particularly noteworthy observation because, when the compounds  $[\text{M}(\text{CO})_3(\text{NCMe})_3]$  ( $\text{M} = \text{Mo}$  or W) were originally prepared in 1962 and isolated,  $\text{I}_2$  was added to them in refluxing methanol and, under these reaction conditions, only an insoluble non-carbonyl-containing compound was obtained. Recently, the addition of half-a-mole equivalent of  $\text{I}_2$  to  $[\text{MoI}_2(\text{CO})_3(\text{NCMe})_2]$  in refluxing acetonitrile yielded the crystallographically characterized non-carbonyl-containing product  $[\text{MoI}_3(\text{NCMe})_3]$  and confirms that careful control of reaction conditions is required to prevent significantly different products being obtained.  $[\text{MoI}_2(\text{CO})_3(\text{NCMe})_2]$  has been crystallographically characterized and shown to have the capped octahedral geometry.<sup>24</sup>

Since its preparation, the compound  $[\text{MoI}_2(\text{CO})_3(\text{NCMe})_2]$  has been shown to display a diverse range of reactivity. The acetonitrile ligands are particularly labile and are readily substituted by a range of neutral donor ligands. Addition of 1 equivalent of ligand  $\text{L}$  displaces 1 acetonitrile molecule and yields initially the seven-coordinate complexes of type  $[\text{MoI}_2(\text{CO})_3(\text{NCMe})\text{L}]$  ( $\text{L} = \text{phosphines}$ , arsines, stibines) (**4**), which depending on the steric and electronic properties of the ligand may lose the second NCMe ligand to afford the iodide-bridged dimers  $[\{\text{Mo}(\mu\text{-I})(\text{CO})_3\text{L}\}_2]$ . A wide range of mixed ligand systems  $[\text{MoI}_2(\text{CO})_3(\text{L})(\text{L}')]]$  ( $\text{L}' = \text{phosphines}$ , arsines, stibines, ureas, thioureas, pyridines etc.) have been prepared through treatment of (**4**) with a second equivalent of a different monodentate ligand  $\text{L}'$ .  $[\text{MoI}_2(\text{CO})_3(\text{NCMe})_2]$  also reacts with a wide range of neutral bidentate ligands to yield *bis*-nitrile substituted products  $[\text{MoI}_2(\text{CO})_3(\text{L-L})]$  (phosphines, bpy etc.). The halide ligands can also be substituted through use of anionic ligands such as thiolates, dithiocarbamates, acac, and so on. The reactivity of this compound is summarized in Scheme 3.

The compounds  $[\text{M}(\text{CO})_3(\text{NCMe})_3]$  have also been shown to undergo oxidative elimination with a range of other halogen-based oxidants including  $\text{Br}_2$ ,  $\text{ICl}$ , and  $\text{IBr}$ , to afford analogous seven-coordinate complexes. The reactivity of these compounds has been less extensively investigated than  $[\text{MoI}_2(\text{CO})_3(\text{NCMe})_2]$ .

#### 2.4.2 Group 14-Containing Halocarbonyl Complexes

These compounds are of particular interest as they have been shown to be active Ring Opening Metathesis Polymerization (ROMP) catalysts (*see Metathesis Polymerization Processes by Homogeneous Catalysis*). They are not, however, as effective as imido-based alkylidene systems (see next section).

Routes for the preparation of these types of compound are similar to the dihalo analogs in the previous section. Thus, the heterobimetallic complexes  $[\text{MoX}(\text{MX}_3)(\text{CO})_3(\text{bpy})]$

**Scheme 3** (i)  $\text{L} = \text{PR}_3$ ,  $\text{AsR}_3$ ,  $\text{SbR}_3$ ,  $\text{BiR}_3$ ,  $\text{OPPh}_3$ ,  $\text{SPPH}_3$ ; (ii)  $\text{L}' = \text{PR}_3$ ,  $\text{AsR}_3$ ,  $\text{SbR}_3$ ,  $\text{BiR}_3$ ,  $\text{OPPh}_3$ ,  $\text{SPPH}_3$ ,  $\text{SC}(\text{NR}_2)_2$ ; (iii)  $\text{L-L} = \text{bpy}$ , 1,10-phen,  $\text{Ph}_2\text{P}(\text{CH}_2)_n\text{PPh}_2$  ( $n = 1-6$ ); (iv)  $\text{NaS}_2\text{CNR}_2$ ,  $\text{KS}_2\text{COEt}$ , acac; (v)  $\text{OPPh}_3$  (vi)  $\text{SPPH}_3$

(M = Ge, Sn; X = Cl, Br) are prepared through oxidative elimination of  $\text{MX}_4$  to the zero-valent precursor  $[\text{Mo}(\text{CO})_4(\text{bpy})]$ . Oxidative elimination of  $\text{MCl}_4$  (M = Sn, Ge) to  $[\text{Mo}(\text{CO})_3(\text{NCMe})_3]$  gives the more versatile, as they contain labile readily substitutable acetonitrile ligands, seven-coordinate complexes  $[\text{MoX}(\text{MX}_3)(\text{CO})_3(\text{NCMe})_2]$ .<sup>21</sup> These compounds have been shown to undergo a wide range of molybdenum-centered substitution chemistry analogous to that reported for  $[\text{MoI}_2(\text{CO})_3(\text{NCMe})_2]$ . Oxidative elimination has also been shown to be facile with  $[\text{Mo}(\text{CO})_4(\text{NCMe})_2]$ ,<sup>25</sup> and the solid-state structure of  $[\text{MoX}(\text{MX}_3)(\text{CO})_3(\text{NCMe})_2]$  has been determined.<sup>26</sup> The structure was shown to contain a chloride ligand bridging the Mo–Sn bond (see *Bridging Ligand*). The reaction between  $[\text{Mo}(\text{CO})_6]$  and  $\text{SnCl}_4$  under photochemical conditions has also been described and shown to yield the crystallographically characterized complex  $[(\text{CO})_4\text{Mo}(\mu\text{-Cl}_3)\text{Mo}(\text{SnCl}_3)(\text{CO})_3]$ .

## 2.5 Alkylidene Complexes

Alkylidene complexes are typically carbene-containing complexes of transition metals in high oxidation states as opposed to low oxidation state Fischer-type carbenes (see *Carbene Complexes*). They tend to be nucleophilic (see *Nucleophile*) in nature as opposed to the electrophilic (see *Electrophile*) Fischer-type carbenes. By far, the most important alkylidene complexes of molybdenum are the imido-containing complexes  $[\text{Mo}(\text{CHR}')(\text{NAr})(\text{OR})_2]$  originally reported by Schrock, and some good reviews of this chemistry are available.<sup>27–29</sup> The synthetic relevance of these compounds means also that some are now commercially available. These compounds have been used successfully for ROMP and Ring Closing Metathesis Polymerization (RCMP) (see *Metathesis Polymerization Processes by Homogeneous Catalysis*). One of the problems, however, associated with these alkylidene complexes is their lack of tolerance to many functional groups. This problem can often be overcome by using ruthenium-based alkylidene systems (see *Ruthenium: Organometallic Chemistry and Carbene Complexes*). A significant advance made recently is the preparation of chiral alkylidene complexes (Figure 3) that act as catalysts for asymmetric ring closing metathesis

**Figure 3** Chiral molybdenum alkylidene complexes used in asymmetric ring closing metathesis polymerization

(see *Metathesis Polymerization Processes by Homogeneous Catalysis*).<sup>30,31</sup> Another is that  $[\text{Mo}\{\text{CH}(\text{CMe}_2\text{Ph})\}(\text{NC}_6\text{H}_3-2,3\text{-}i\text{Pr}_2)\{\text{OC}(\text{Me})(\text{CF}_3)_2\}_2]$  is capable of effecting both ROMP and RCMP in liquid and supercritical  $\text{CO}_2$ .<sup>32</sup> This approach has particular attractions: the ease with which  $\text{CO}_2$  can be removed from the polymer and there is no waste organic solvent that needs to be disposed of.

## 2.6 Alkylidyne Complexes<sup>33</sup>

$[\text{Mo}(\text{CBu}')(\text{CH}_2\text{Bu}')_3]$  was first prepared in a low yield from the reaction between  $t\text{BuCH}_2\text{Li}$  and  $\text{MoCl}_5$ . An improved synthesis is available in which  $\text{MoO}_2\text{Cl}_2$  is added to the Grignard reagent  $t\text{BuCH}_2\text{MgBr}$  at  $-78^\circ$  in diethylether. It is most likely that the alkylidyne ligand is formed through successive  $\alpha$ -elimination processes (see  *$\alpha$ -Elimination*). Another route to alkylidyne complexes is through alkyne metathesis reactions (see *Metathesis Polymerization Processes by Homogeneous Catalysis*) with the triply bonded dimer  $[\text{Mo}_2(\text{OBu}')_6]$  and alkynes to give  $[\text{Mo}\equiv\text{CR}(\text{OBu}')_3]$ , however, terminal alkynes are not successfully converted to alkylidyne complexes by this method. This type of complex has been shown to be important as ROMP and RCMP catalysts (see *Metathesis Polymerization Processes by Homogeneous Catalysis*); however, their use has been severely limited as a result of the difficulty in their synthesis. This situation may soon change because of the discovery of a new and effective route to their preparation (equation 6). The ene-dialkylidyne complex 1,2-di $(-\text{C}\equiv\text{MoL}_n)$ cyclohex-1-ene has recently been synthesized and crystallographically characterized and the average  $\text{Mo}\equiv\text{C}$  bond length was found to be  $1.753(5)\text{ \AA}$  (Figure 4).<sup>34</sup>

**Figure 4** Molecular structure of 1,2-di $(-\text{C}\equiv\text{MoL}_n)$ cyclohex-ene. (Reprinted with permission from Ref. 34. © 2003 American Chemical Society)

### 3 $\pi$ -LIGAND-CONTAINING COMPLEXES

#### 3.1 Alkene and Allyl Complexes

Alkene complexes of the type  $[\text{Mo}(\text{CO})_{(6-n)}(\eta^2\text{-H}_2\text{C}=\text{CH}_2)_n]$  ( $n = 1, 2$ ) have been known since 1963 and are prepared by the photolysis of  $[\text{Mo}(\text{CO})_6]$  (see **Photochemistry of Transition Metal Complexes**) in the presence of an alkene. The geometry of the *bis*-alkene complexes synthesized is *trans*, with the alkenes orientated orthogonal to each other. Matrix isolation studies (see *Matrix Isolation*) suggest that on photodissociation of CO from  $[\text{Mo}(\text{CO})_5(\eta^2\text{-alkene})]$  it is a *cis* carbonyl ligand that dissociates. This means that there is subsequent rearrangement to the observed *trans* product. The original assignment of the *trans* geometry was based upon the observation of a single  $\nu(\text{CO})$  band in the IR spectrum, which is consistent with gross  $D_{4h}$  symmetry (see **Surfaces**); the *cis* geometry has  $C_{2v}$  symmetry and would be expected to give rise to four bands. When butadiene, which is a conjugated diene and has the potential to act as a chelating ligand, is the alkene ligand only one of the double bonds is initially involved in bonding to the metal center and the *bis-trans*- $[\text{Mo}(\text{CO})_4(\eta^2\text{-CH}_2=\text{CHCH}=\text{CH}_2)_2]$  complex can be prepared. This compound can be transformed into the *bis-cis*- $[\text{Mo}(\text{CO})_2(\eta^2\text{-CH}_2=\text{CHCH}=\text{CH}_2)_2]$  complex on warming.<sup>35</sup>

The analogous *bis*-ethene-containing complex *trans*- $[\text{Mo}(\text{PMe}_3)_4(\eta^2\text{-ethene})_2]$  is prepared on bubbling ethene through a solution of  $[\text{Mo}(\text{PMe}_3)_4(\text{N}_2)_2]$ , and it has been crystallographically characterized (Figure 5).<sup>36</sup> It can be clearly seen that the ethene ligands are *trans* and orthogonal to each other. This means each ligand accepts electron density from a different metal  $d\pi$  orbital and so maximizes  $\pi$ -backbonding into its  $\pi^*$ -antibonding molecular orbital. Each ethene ligand also orientates so it eclipses a P–Mo–P vector. The average Mo–C bond length is 2.270(6) Å.

The reactivity of  $[\text{Mo}(\text{PMe}_3)_4(\eta^2\text{-ethene})_2]$  has been much studied and, for example, the *tris*-alkene-containing compound  $[\text{Mo}(\text{PMe}_3)(\eta^3\text{-H}_2\text{C}=\text{CH}-\text{COOMe})_3]$  is prepared on treatment with  $\text{H}_2\text{C}=\text{CH}-\text{COOMe}$  and it has been crystallographically characterized (Figure 6). The structure

**Figure 5** Molecular structure of  $[\text{Mo}(\text{PMe}_3)_4(\eta^2\text{-H}_2\text{C}=\text{CH}_2)_2]$ . (Reprinted with permission from Ref. 36. © 2003 American Chemical Society)

**Figure 6** Molecular structure of  $[\text{Mo}(\text{PMe}_3)(\text{H}_2\text{C}=\text{CHCO}_2\text{Me})_3]$ . (Reprinted from Ref. 37, with permission from Elsevier)

shows two of the methylacrylate ligands coordinate through their C=C and C=O bonds and the third through the C=C bond only. It is noteworthy that in this structure, as in the parent compound, the mutually *trans* alkene ligands are again orientated orthogonal to each other.<sup>37</sup>

Since its discovery in the 1980s,  $\text{C}_{60}$  (Buckminsterfullerene) (see **Carbon: Fullerenes**) has captured the imagination. It has been shown to coordinate to many transition metals including molybdenum centers as a two-electron donor alkene ligand. For example, the reaction between *mer*- $[\text{Mo}(\text{CO})_3(\text{NCMe})_3]$  with dppb (*bis*-diphenylphosphinobutane) followed by  $\text{C}_{60}$  gives *mer*- $[\text{Mo}(\text{CO})_3(\eta^2\text{-C}_{60})(\text{dppb})]$ .<sup>38</sup>  $\text{C}_{60}$  has been shown to coordinate up to three  $[\text{Mo}(\text{CO})_2(\text{phen})(\text{dbm})]$  moieties and each of the compounds is electrochemically active at  $\text{C}_{60}$  (see **Electrochemistry: Applications in Inorganic Chemistry**) and at more negative potentials than for uncoordinated  $\text{C}_{60}$ . *mer*- $[\text{Mo}(\text{CO})_3(\eta^2\text{-C}_{60})(\text{dppb})]$  shows three one-electron reduction potentials associated with the  $\text{C}_{60}$  ligand. A fourth

one-electron reduction is also observed, which is metal centered and causes dissociation of the  $C_{60}$  ligand. Similar behavior is seen when the fullerene  $C_{70}$  is coordinated to a metal center.<sup>39</sup>

The reaction between chelating-unconjugated dienes like norbornadiene (NBD) or cycloocta-1,5-diene (COD) yields the compounds *cis*-[Mo(CO)<sub>4</sub>( $\eta^2$ ,  $\eta^2$ -alkene)]. These products are considerably more stable than their mono-ene analogs due to the chelate effect (*see Chelate Effect*). They are often used as precursors for the preparation of [Mo(CO)<sub>4</sub>L<sub>2</sub>] complexes as better yields and purer products are obtained than from the direct reaction between [Mo(CO)<sub>6</sub>] and L at elevated temperatures. For example, the fluorophosphine complex [Mo(CO)<sub>4</sub>{PF<sub>2</sub>(CPh<sub>3</sub>)<sub>2</sub>}] can be prepared on stirring [Mo(CO)<sub>4</sub>(NBD)] with PF<sub>2</sub>(CPh<sub>3</sub>) at room temperature for 1 h. The solid-state structure of this compound reveals very short Mo–P bonds (2.429 Å) (expected  $\approx$  2.58 Å) and is due to the presence of the electronegative (*see Electronegativity*) fluorine atoms.<sup>40</sup> Dienes are also known to coordinate to molybdenum in higher oxidation states. The seven-coordinate complex [Mo(SnCl<sub>3</sub>)Cl(CO)<sub>3</sub>( $\eta^4$ -NBD)] was prepared on reaction between [(CO)<sub>4</sub>Mo( $\mu$ -Cl)<sub>3</sub>MoSnCl<sub>3</sub>(CO)<sub>3</sub>] with a stoichiometric amount of NBD (equation 7). Its solid-state structure shows some interesting structural features, the most significant being the asymmetry in the bond lengths to the NBD ligand. The alkene trans to the Cl ligand has Mo–C bond lengths of 2.330(3) Å and 2.335(3) Å respectively, which are approximately 0.1 Å shorter than those trans to CO, 2.431(3) Å and 2.423(3) Å. This is consistent with the relative  $\pi$ -acidities of the ligands CO > R<sub>2</sub>C=CR<sub>2</sub> > Cl<sup>–</sup> and equally accounts for the differences in the bound C=C bond lengths, 1.388(4) Å and 1.362(4) Å trans to Cl and CO respectively. [Mo(SnCl<sub>3</sub>)Cl(CO)<sub>3</sub>( $\eta^4$ -NBD)] has also been shown to initiate ROMP of NBD when treated with an excess of NBD (*see Metathesis Polymerization Processes by Homogeneous Catalysis*). The propagation step in the polymerization was found to be slower than the initiation step, which requires decomplexation of one alkene moiety of the NBD ligand followed by rearrangement to an alkylidene ligand with subsequent ring opening followed by a 1,2-hydrogen shift.<sup>41,42</sup>

**Figure 7** Different isomers of [CpMo( $\eta^3$ -C<sub>3</sub>H<sub>5</sub>)( $\eta^4$ -C<sub>4</sub>H<sub>6</sub>)]

The compounds [CpMo<sup>(II)</sup>( $\eta^4$ -C<sub>4</sub>H<sub>6</sub>)<sub>2</sub>]<sup>+</sup>, [CpMo<sup>(III)</sup>( $\eta^3$ -C<sub>3</sub>H<sub>5</sub>)<sub>2</sub>], [CpMo<sup>(II)</sup>( $\eta^3$ -C<sub>3</sub>H<sub>5</sub>)( $\eta^4$ -C<sub>4</sub>H<sub>6</sub>)], [CpMo<sup>(III)</sup>( $\eta^3$ -C<sub>3</sub>H<sub>5</sub>)( $\eta^4$ -C<sub>4</sub>H<sub>6</sub>)]<sup>+</sup> have all been prepared.<sup>43,44</sup> For [CpMo<sup>(III)</sup>( $\eta^3$ -C<sub>3</sub>H<sub>5</sub>)( $\eta^4$ -C<sub>4</sub>H<sub>6</sub>)]<sup>n+</sup> ( $n = 0, 1$ ), four different isomeric forms are possible (Figure 7a–d). The allyl ligand adopts a *prone* or *exo* (Figure 7a and 7d) *supine* or *endo* (Figure 7b and 7c) geometry, whereas the butadiene ligand takes either *s-cis supine* (Figure 7a and 7d) or *s-trans* (Figure 7c and 7d). The *s-cis prone* butadiene ligand geometry has not been observed for this system. Depending upon the oxidation state Mo<sup>(II)</sup> versus Mo<sup>(III)</sup> diamagnetic, 18-valence electron or 17-valence electron paramagnetic species are obtained. This change in electronic configuration and metal oxidation state has a profound effect on their reactivity, for example see Scheme 4.<sup>43</sup> The related diene complexes [CpMoCl<sub>2</sub>( $\eta^4$ -diene)] (diene = butadiene, isoprene) react with Grignard reagents in a metathetical reaction to yield dialkyl complexes of the type [CpMoR<sub>2</sub>( $\eta^4$ -diene)] (R = Me, CH<sub>2</sub>Ph, CH<sub>2</sub>SiMe<sub>3</sub>), note the absence of  $\beta$ -hydrogen atoms, rather than nucleophilic (*see Nucleophile*) attack at the diene ligand. The new Mo–C bonds are stable to weak acids but are cleaved by HCl, HBF<sub>4</sub>, and CF<sub>3</sub>CO<sub>2</sub>H.<sup>45</sup>

An example of nucleophilic attack (*see Nucleophile*) on a  $\pi$ -bound diene is illustrated in Scheme 5. The incoming nucleophile adds on the face *exo* (*see Exo & Endo Substituents*) to the metal, meaning the metal has an antirecting effect (*see Organic Synthesis using Transition Metal Complexes Containing  $\pi$ -Bonded Ligands*). The functionalized organic molecule can then be obtained through oxidative cleavage; note the iodide enters on the same face as the nucleophile.<sup>46</sup>

**Scheme 4** Different reactivity caused by change in oxidation state (a) Mo<sup>II</sup>, (b) Mo<sup>III</sup>

**Scheme 5** An example of a nucleophilic attack on a  $\pi$ -bound diene

**Figure 8** General structure of  $[\text{MoX}(\text{CO})\text{L}_2(\eta^3\text{-C}_3\text{H}_5)]$

$\pi$ -Allyl complexes of the type  $[\text{MoX}(\text{CO})_2(\text{L})_2(\eta^3\text{-allyl})]$  behave similarly to diene complexes. They show both metal- and ligand-centered reactivity. One method used to prepare this class of compound is by an oxidative elimination reaction between  $[\text{Mo}(\text{CO})_3(\text{L})_3]$  ( $\text{L} = \text{DMF}, \text{NCMe}, \text{Py}$ ) and a suitable allyl halide or allyl acetate to give  $[\text{MoX}(\text{CO})_2(\text{L})_2(\eta^3\text{-allyl})]$  ( $\text{X} = \text{Cl}, \text{Br}, \text{acetate}$ ).<sup>47</sup> The ligands  $\text{L}$  maybe exchanged for a range of monodentate ( $\text{L}'$ ) and bidentate ligands ( $\text{L-L}$ ); nucleophiles (*see Nucleophile*) may also attack the allyl moiety leading to functionalized allylic products.<sup>48</sup> These pseudooctahedral complexes are also known to be fluxional in solution with three different processes having been identified using VT NMR spectroscopy (*see Stability Constants & their Determination*), a pivoted double-switch mechanism, intramolecular trigonal twist, and slow dissociative ligand exchange.<sup>49</sup> They also all generally have the same solid-state geometry (Figure 8). Another interesting use that has recently been found for compounds of the type  $[\text{CpMo}(\text{CO})_2(\eta^3\text{-allyl})]$  is as robust markers in peptide systems.<sup>50</sup>

Complexes of cycloheptatriene ( $\text{C}_7\text{H}_8$ ) and the tropylium cation ( $\text{C}_7\text{H}_7^+$ ) are also known and their chemistry mirrors that of the smaller polyene-containing systems, namely, metal-centered ligand exchange reactions and ligand-centered nucleophilic attack. A detailed review of this chemistry is available.<sup>51</sup>

### 3.2 Alkyne-containing Complexes

Alkyne complexes of molybdenum are common and there are several approaches to their preparation. They are of

particular interest as the alkyne has the potential to act as a variable electron donor to the metal center: 4-e, 3-e or 2-e. The alkyne is able to act as a variable electron donor as it has two orthogonal  $\pi$ -systems, which may participate in bonding to the metal center. This makes them noticeably different from mono-alkene ligands, which can behave only as 2-e donors.

Much work has centered on coordination of alkynes to the  $[(\eta^5\text{-C}_5\text{H}_5)\text{Mo}]$  moiety. *Bis*-alkyne-containing complexes of the type  $[\text{CpMo}(\text{CO})(\eta^2\text{-alkyne})_2]$  are readily synthesized, for example, on reaction of  $[\{\text{CpMo}(\text{CO})_3\}_2]$  with 2 Mole equivalents of alkyne in the presence of  $\text{Ag}^+$ . The alkyne ligands in these complexes are formally 3-e donors, if the complex is to obey the EAN (*see Effective Atomic Number Rule*). The compounds show a wide range of metal-centered ligand substitution reactions with, for example, phosphines and phosphites. It has also been shown that it is possible to react the coordinated alkyne with a range of nucleophiles (*see Nucleophile*). The related mono-alkyne-containing complexes  $[\text{CpMoL}(\eta^2\text{-RC}_2\text{R})_2]$  ( $\text{L} = \text{phosphine or phosphite}$ ) are readily converted to either allyl- or metallacyclopropene-containing complexes on treatment with nucleophiles. The *bis*-alkyne-containing complexes undergo a diverse array of ligand coupling reactions and some reviews with regard to these reactions are available.<sup>19,52,53</sup>  $[\text{Mo}(\text{CO})(\eta^2\text{-PhC}\equiv\text{CPh})\text{Cp}][\text{BF}_4]$  reacts with 3 equivalents of  $\text{CNBu}^t$  to give  $[\text{Mo}(\text{CNBu}^t)_3(\eta^2\text{-PhC}\equiv\text{CPh})\text{Cp}][\text{BF}_4]$ , where the alkyne has switched from a 4-e to a 2-e donor. Addition of a fourth equivalent of  $\text{CNBu}^t$  causes a coupling reaction to occur ultimately affording a vinylcarbene. Reduction with  $\text{Na/Hg}$  has been shown to give different products that are condition dependent (Scheme 6).<sup>54</sup> Heptamethylindenyl analogs have also recently been prepared and shown to display similar reactivity to the parent cyclopentadienyl complexes.<sup>55</sup>

Making use of the isolobal analogy (*see Isolobal Analogy*), it has been shown that the imido group ( $\text{NR}$ ) is isolobal with the cyclopentadienyl moiety. Bearing this relationship in

**Scheme 6** Isonitrile/alkyne coupling reactions;  $\text{L} = \text{CNBu}^t$

mind, the *bis*-imido alkyne complexes  $[\text{Mo}(\text{NR})_2(\text{PMe}_3)(\eta^2\text{-R}'\text{C}\equiv\text{CR}'')] [\text{R} = \text{Ph or adamantyl, R}' = \text{R}'' = \text{Ph; R} = \text{'Bu, R}' = \text{Ph, R}'' = \text{H}]$  were prepared by displacement of ethene from the analogous alkene complexes  $[\text{Mo}(\text{NR})_2(\text{PMe}_3)(\eta^2\text{-H}_2\text{C}=\text{CH}_2)]$  in hot heptane. The solid-state structure of  $[\text{Mo}(\text{N}'\text{Bu})_2(\text{PMe}_3)(\eta^2\text{-PhC}\equiv\text{CPh})]$  was reported and shows the molecule is pseudo-tetrahedral. The alkyne contact carbon atoms and phosphorus atoms are all coplanar and this plane is perpendicular to the plane defined by N-Mo-N. Analogous structural characteristics are observed in the related solid-state structure of  $[\text{Mo}(\text{N}'\text{Bu})_2(\text{PMe}_3)(\eta^2\text{-HC}\equiv\text{CMe})]$  and in zirconocene systems (see **Zirconium & Hafnium: Organometallic Chemistry**). These data add strong support for the isolobal relationship between zirconocenes and four-coordinate *bis*-imido complexes of molybdenum.<sup>56</sup>

The preparation of the *bis*-alkyne complexes  $[\text{Wl}_2(\text{CO})(\text{NCMe})(\eta^2\text{-RC}\equiv\text{CR})_2]$  was reported in 1988 and their reactivity has been reviewed.<sup>21</sup> The analogous molybdenum complexes  $[\text{MoXX}'_2(\text{CO})(\text{NCMe})(\eta^2\text{-RC}\equiv\text{CR}')_2]$  ( $\text{X} = \text{X}' = \text{I, Br; X} = \text{I, X}' = \text{Cl; R} = \text{R}' = \text{Me, Ph; R} = \text{Me, R}' = \text{Ph}$ ), which are less stable than the related tungsten analogs, were isolated and structurally characterized in 1998.<sup>57</sup> The structure of  $[\text{MoI}_2(\text{CO})(\text{NCMe})(\eta^2\text{-MeC}\equiv\text{CMe})_2]$  shows the molecule to be pseudooctahedral, if the alkyne ligands are assumed to occupy one coordination site. The  $\text{C}\equiv\text{C}$  vectors run parallel to the M-CO axis, which is a common structural feature in compounds of this type. The methyl groups bend away from the linear conformation expected in alkynes due to back bonding from suitable metal  $d\pi$  orbitals into the  $\pi^*$ -antibonding molecular orbitals of the alkyne ligands. The reactivity of these compounds with regard to ligand substitution reactions has been described and reviewed.<sup>21</sup> For example, on reaction with the monodentate phosphite ligands, initial substitution of an alkyne occurs affording  $[\text{MoI}_2(\text{CO})\{\text{P}(\text{OR})_3\}(\text{NCMe})(\eta^2\text{-RC}_2\text{R})]$  that on subsequent treatment with a second equivalent gives rise to a mixture of *cis*- and *trans*-phosphite isomers  $[\text{MoI}_2(\text{CO})\{\text{P}(\text{OR})_3\}_2(\eta^2\text{-RC}_2\text{R})]$ ; in neither isomer is the alkyne found *trans* to the carbonyl ligand.<sup>58</sup> The alkyne ligand in *cis*- $[\text{MoI}_2(\text{CO})\{\text{P}(\text{OMe})_3\}_2(\eta^2\text{-MeC}_2\text{Me})]$  was shown to be fluxional and undergoing propeller-like rotation, which could be frozen out at low temperature (see **Stability Constants & their Determination**). The barrier to rotation  $\Delta G^\ddagger$  was calculated to be  $55 \text{ kJ mol}^{-1}$ .

In the compounds  $[\text{CpMoL}_2(\eta^2\text{-MeC}_2\text{Me})]^{z+}$  ( $\text{L} = \text{phosphorus donor, } z = 0, 1$ ), the but-2-yne ligand was shown to undergo propeller-like rotation (Figure 9a): at high temperature a single methyl resonance was observed in the  $^1\text{H}$  NMR spectrum and at low temperatures gave two signals for the methyl groups due to the asymmetric environment. The solid-state structures of this class of compound, that have been determined crystallographically, all have the  $\text{C}\equiv\text{C}$  vector of the alkyne parallel to an Mo-P vector. This means, if the alkyne propeller-like rotation is frozen out, two signals should be evident in the  $^{31}\text{P}$  NMR spectrum due to the presence of

inequivalent phosphorus environments. For these compounds, this was found not to be the case and a second associated oscillation was shown to be taking place (Figure 9b) (see **Stability Constants & their Determination**).<sup>59</sup>

### 3.3 Phosphaalkyne Complexes of Molybdenum

Phosphaalkynes ( $\text{RC}\equiv\text{P}$ ) are phosphorus analogs of nitriles and have been shown to display a diverse range of organic- and inorganic-based chemistry including the preparation of phosphaalkyne-containing-transition metal complexes. This work has been reviewed.<sup>60</sup> Photoelectron spectroscopy has shown that the Highest Occupied Molecular Orbital (HOMO) is the phosphorus-carbon triple bond. It is this that influences the coordination chemistry of these molecules and why  $\pi$ -coordination is found to dominate  $\sigma$ -coordination. As a result, these complexes tend to parallel the well-known  $\pi$ -bound alkyne systems rather than their lighter congeners, the nitriles, which generally prefer the  $\sigma$ -ligation mode, for example, in  $[\text{Mo}(\text{CO})_3(\text{NCMe})_3]$ . However,  $\pi$ -bound nitriles are known and the first crystallographically characterized example was  $[\text{Cp}_2\text{Mo}(\eta^2\text{-NCMe})]$  reported by Wilkinson in 1986. The related compound  $[(\eta^5\text{-C}_5\text{H}_4\text{Bu}')_2\text{Mo}(\eta^2\text{-NCMe})]$  has recently been synthesized and crystallographically characterized. The lone pair at nitrogen has been shown to react with alkyl halides to give the cationic iminoacyl products  $[(\eta^5\text{-C}_5\text{H}_4\text{Bu}')_2\text{Mo}(\eta^2\text{-RN}=\text{CMe})][\text{I}]$  ( $\text{R} = \text{Me, Et}$ ).<sup>61</sup>

End-on  $\sigma$ -coordination of phosphaalkynes has been affected by careful control of the steric environment (see **Steric Effect**) at the metal center or the steric bulk of the phosphaalkyne, thus treatment of  $[\text{Mo}(\text{N}_2)_2\{\text{Et}_2\text{P}(\text{CH}_2)_2\text{PEt}_2\}_2]$  with 2 equivalents of  $\text{'BuCP}$  afforded the dinitrogen displaced product  $[\text{Mo}(\text{P}\equiv\text{CBu}')_2\{\text{Et}_2\text{P}(\text{CH}_2)_2\text{PEt}_2\}_2]$ . More recently, the very bulky supermesityl-phosphaalkyne  $\text{P}\equiv\text{CMes}^*$  ( $\text{Mes}^* = \text{-C}_6\text{H}_2\text{Bu}'_3$ ) has been reacted with  $[\text{Mo}(\text{CO})_3(\text{PCy}_3)_2]$  to give the  $\eta^1$ -phosphaalkyne bound compound  $[\text{Mo}(\text{CO})_3(\text{PCy}_3)_2(\eta^1\text{-P}\equiv\text{CMes}^*)]$ .<sup>62</sup> The crystal structure of the analogous tungsten complex shows that

**Figure 9** Two fluxional processes present in  $[\text{CpMoL}_2(\eta^2\text{-RC}_2\text{R})]$

the P–C triple bond length (1.54 Å) is little affected on coordination.

The first example of a  $\pi$ -bond phosphalkyne complex was  $[\text{Pt}(\text{PPh}_3)_2(\eta^2\text{-PCBu}^t)]$ . The lone pair located at the phosphorus atom allows further elaboration. Thus, treatment with  $[\text{Mo}(\text{CO})_5(\text{THF})]$  afforded the bimetallic complex  $[\text{Pt}(\text{PPh}_3)_2\{\eta^2\text{-Bu}^t\text{CP} \rightarrow \text{Mo}(\text{CO})_5\}]$ . In other parallels to alkyne chemistry treatment of  $[\{\text{CpMo}(\text{CO})_2\}_2]$  with  $^t\text{BuCP}$  affords the four-electron donor phosphalkyne complex  $[\{\text{CpMo}(\text{CO})_2\}(\mu\text{-}\eta^2\text{:}\eta^2\text{-PCBu}^t)\{\text{CpMo}(\text{CO})_2\}]$ . This compound was shown to undergo further reaction at the phosphorus lone pair, including the formation of adducts with  $[\text{Fe}_2(\text{CO})_9]$ ,  $[\text{W}(\text{CO})_5(\text{THF})]$  and  $[\text{Os}_3(\text{CO})_{11}(\text{NCMe})]$ .

In addition to affording analogous products of the alkyne-containing complexes, some significant differences are also noted. Treatment of  $[(\eta^5\text{-C}_9\text{H}_7)\text{Mo}(\text{CO})_2(\text{NCMe})_2][\text{BF}_4]$  with 2 equivalents of  $\text{MeC}_2\text{Me}$  affords the *bis*-alkyne complex  $[(\eta^5\text{-C}_9\text{H}_7)\text{Mo}(\text{CO})(\eta^2\text{-MeC}_2\text{Me})_2][\text{BF}_4]$  in which the alkynes behave on average as 3e-donors. Whereas treatment of  $[(\eta^5\text{-C}_9\text{H}_7)\text{Mo}(\text{CO})_2(\text{NCMe})_2][\text{BF}_4]$  with 2 Molar equivalents of  $^t\text{BuCP}$  afforded a  $\eta^3$ -ligated 1,3-diphosphacyclobutadiene-containing complex, which in the solid-state has a nonplanar diphosphacyclobutadiene ring. The loss of planarity is caused by one of the phosphorus atoms in the diphosphacyclobutadiene ring interacting with the  $[\text{BF}_4]^-$  counteranion: P–F 1.536(5) Å (Figure 10a). This interaction leads to the positive charge residing at phosphorus and an elongation of the B–F bond to 1.477(11) Å with the average of the other three B–F bonds being 1.333 Å. It was proposed from the spectroscopic data that in solution the molecule adopts an  $\eta^4$ -ligation of the diphosphacyclobutadiene moiety due to the presence of a singlet resonance in its  $^{31}\text{P}\{-^1\text{H}\}$  NMR spectrum  $\delta$ -121.1 ppm.<sup>63</sup>

It is well known that alkynes may behave as variable electron donors to metal centers and efforts have been made to prepare (nonbridging) 4e-donor phosphalkyne-containing complexes. Treatment of the *trans*-stilbene complex (5) with a stoichiometric amount of  $^t\text{BuCP}$  afforded the low-melting green solid (6). Further, treatment of this 4e-donor phosphalkyne complex with another molar equivalent of  $^t\text{BuCP}$  afforded the 1,3-diphosphacyclobutadiene-containing complex (7) in good overall yield and showed the possibility

**Scheme 7** Stepwise formation of a diphosphabutadiene ring

of the stepwise formation of 1,3-diphosphacyclobutadiene complexes (Scheme 7).<sup>64</sup>

Using a similar approach, the *bis*-trimethylphosphite-containing complex  $[\text{CpMo}\{\text{P}(\text{OMe})_3\}_2(\eta^2\text{-P}\equiv\text{CBu}^t)]$ , analog of (6), was obtained in good yield. Unfortunately, a solid-state structure could not be obtained, for what is rare example of a 4e-donor phosphalkyne complex of  $\text{Mo}^{\text{II}}$ , so a theoretical calculation on the model compound  $[(\eta^5\text{-C}_5\text{H}_5)\text{Mo}\{\text{P}(\text{OH})_3\}_2(\eta^2\text{-P}\equiv\text{CMe})]^+$  was carried out and the data obtained were comparable to that obtained for the crystallographically determined solid-state structure of the analogous alkyne-containing complex  $[\text{CpMo}\{\text{P}(\text{OMe})_3\}_2(\eta^2\text{-HC}_2\text{Bu}^t)]^+$ , where the alkyne is orientated parallel to a Mo–P vector. The short nature of the calculated Mo–C bond distance (2.06 Å) to the ligated phosphalkyne is consistent with the phosphalkyne being considered a 4e-donor and indeed is comparable to the structural characterization of a 4e-donor phosphalkyne in the related tantalum complex  $[(\eta^5\text{-C}_5\text{Me}_5)\text{TaCl}_2(\eta^2\text{-P}\equiv\text{CBu}^t)]$  (see *Niobium & Tantalum: Inorganic & Coordination Chemistry*). Further, treatment of  $[\text{CpMo}\{\text{P}(\text{OMe})_3\}_2(\eta^2\text{-PCBu}^t)][\text{B}(\text{C}_6\text{F}_5)_4]$  with a stoichiometric amount of  $\text{PCBu}^t$  afforded the 1,3-diphosphacyclobutadiene-containing complex  $[\text{CpMo}\{\text{P}(\text{OMe})_3\}(\eta^4\text{-P}_2\text{C}_2\text{Bu}_2^t)][\text{B}(\text{C}_6\text{F}_5)_4]$ . The mechanism of the reaction was suggested to be associative because of the potential of the 4e-donor phosphalkyne to switch to

**Figure 10** 1,3-Diphosphacyclobutadiene complexes of molybdenum

become a 2e-donor, which is common behavior for 4e-donor alkyne ligands in equivalent alkyne-containing complexes, thus forming a site of attack for the incoming phosphaaalkyne. These data add additional support to the stepwise formation of 1,3-diphosphacyclobutadiene rings at molybdenum.<sup>65</sup>

Other routes to 1,3-diphosphacyclobutadiene-containing complexes of molybdenum have been described. Treatment of  $[(\eta^5\text{-C}_5\text{R}_5)\text{MoCl}(\text{CO})_3]$  (where R = H, Me) with  $\text{PCBu}'$  afforded the 1,3-diphosphacyclobutadiene-containing complexes  $[(\eta^5\text{-C}_5\text{R}_5)\text{MoCl}(\text{CO})(\eta^4\text{-1,3-P}_2\text{C}_2\text{Bu}'_2)]$  (where R = H, Me) (**8**), (**9**) in reasonable yield. Again this mode of reactivity differs from that of alkynes, where on treatment of  $[(\eta^5\text{-C}_5\text{R}_5)\text{MoCl}(\text{CO})_3]$  (where R = H, Me) with  $\text{RC}_2\text{R}$  affords the 4e-donor alkyne-containing complexes  $[(\eta^5\text{-C}_5\text{R}_5)\text{MoCl}(\text{CO})(\eta^2\text{-RC}_2\text{R})]$ . The asymmetry at the metal center gives rise to two  $\text{Bu}'$  signals in the  $^1\text{H}$  NMR spectrum at room temperature, which on warming begin to coalesce at 60 °C at 400 MHz (see *Stability Constants & their Determination*). Compound (**8**) reacts slowly with water at one of the coordinated phosphorus atoms in an oxidative addition reaction to give compound (**10**) (Figure 10b), which has been crystallographically characterized showing the hydroxyl moiety to be *exo* (see *Exo & Endo Substituents*).<sup>66</sup>

Metal centers are known to trimerize alkynes to give functionalized arenes and attempts, using molybdenum-based systems, have been made to try and prepare triphosphabenzene. An early and unsubstantiated report for the preparation of a 1,3,5-triphosphabenzene-containing complex was reported in the 1980s.<sup>67</sup> An alternative approach used was Metal Vapor Synthesis (see *Metal Vapor Synthesis of Transition Metal Compounds*) in which molybdenum atoms were cocondensed with  $\text{PCBu}'$  at 77 K. The resulting product was  $[\text{Mo}(\eta^4\text{-1,3-P}_2\text{C}_2\text{Bu}'_2)_3]$  that contains three 1,3-diphosphacyclobutadiene rings rather than the hoped for  $[\text{Mo}(\eta^6\text{-P}_3\text{CBu}'_3)_2]$ , which would contain two 1,3,5-triphosphabenzene ligands. The compound has been crystallographically characterized and shows that one of the four-membered rings is rotated through 90° relative to the other two, presumably to reduce steric pressure within the coordination sphere, Figure 10(c).<sup>68</sup>

### 3.3 Cyclopentadienyl-containing complexes

#### 3.3.1 Monocyclopentadienyl Complexes

Molybdenum complexes that contain the cyclopentadienyl ligand ( $\text{C}_5\text{H}_5$ )<sup>−</sup> are very common and the cyclopentadienyl ligand (Cp) is often present as a spectator ligand occupying three coordination sites. Precursor compounds that are often used in Cp-containing molybdenum chemistry are the dimeric complex  $[\{\text{CpMo}(\text{CO})_3\}_2]$ , which contains an unsupported metal–metal bond (3.24 Å),  $[\text{CpMoX}(\text{CO})_3]$  (X = halogen), the anion  $[\text{CpMo}(\text{CO})_3]^-$ , and  $[\text{Cp}_2\text{MoX}_2]$  (X = halogen, hydride etc.).

*Preparation and Reactivity of  $[\{\text{CpMo}(\text{CO})_3\}_2]$ .*  $[\{\text{CpMo}(\text{CO})_3\}_2]$  can be prepared from the reaction between  $[\text{Mo}(\text{CO})_6]$  and dicyclopentadiene at 110 to 120 °C; however, this is only really effective for small scale preparations. Better yields are obtained from the reaction between  $[\text{Mo}(\text{CO})_3(\text{NCMe})_3]$  with  $\text{C}_5\text{H}_6$  monomer or through oxidation of  $[\text{CpMo}(\text{CO})_3]^-$  with iron (III) sulfate.<sup>69</sup> These latter routes are particularly effective for substituted cyclopentadienyls and indenyl.

The reactivity of  $[\{\text{CpMo}(\text{CO})_3\}_2]$  centers around CO substitution by two-electron donors such as phosphines, phosphites, or isonitriles. Typically, one or two carbonyl groups are substituted to give the following compounds  $[\text{CpMo}(\text{CO})_3\text{-Mo}(\text{CO})_2\text{LCp}]$  and  $[\text{CpMo}(\text{CO})_2\text{L-Mo}(\text{CO})_2\text{LCp}]$ . These reactions can be affected either photochemically or thermally (see *Photochemistry of Transition Metal Complexes*). A competing reaction that is often present and difficult to predict is heterolytic cleavage (see *Heterolytic Cleavage*) of the Mo–Mo bond (equation 8).

One carbonyl ligand can also be lost from each molybdenum center in  $[\{\text{CpMo}(\text{CO})_3\}_2]$  in the absence of nucleophiles (see *Nucleophile*), affording the compound  $[\text{Cp}(\text{CO})_2\text{Mo}\equiv\text{Mo}(\text{CO})_2\text{Cp}]$ , which contains a Mo–Mo triple bond. Analogous systems where the Cp ligand is replaced by indenyl and a variety of substituted cyclopentadienes are known and react similarly.<sup>70</sup> This unsaturated compound is very reactive and adds nucleophiles (see *Nucleophile*) under very mild conditions. For example, alkynes add across the triple bond to give  $[\text{Cp}(\text{CO})_2\text{Mo}(\mu\text{-}\eta^2 : \eta^2\text{-RC}_2\text{R})\text{Mo}(\text{CO})_2\text{Cp}]$  and in turn are reactive species. Recently, heterobimetallic complexes of the type  $[\text{Cp}(\text{CO})_2\text{Mo}(\mu\text{-}\eta^2 : \eta^2\text{-RC}_2\text{R})\text{Co}(\text{CO})_3]$  (see *Dinuclear Organometallic Cluster Complexes*) have been prepared and shown to undergo the Pauson–Khand reaction (see *Organic Synthesis using Transition Metal Complexes Containing  $\pi$ -Bonded Ligands*) to make cyclopent-2-enones.<sup>71</sup> The chirality (see *Chiral*) of the tetrahedral metal-alkyne core in these compounds has been shown to give good stereocontrol in asymmetric variants.<sup>72</sup> Reaction with sulfur-containing compounds gives rise to compounds of type (**11**), (**12**), and (**13**). This work has been developed because of its relevance to sulfur rich metal centers in enzymes and important industrial desulfurization processes (see *Hydrodesulfurization & Hydrodenitrogenation*) and has been reviewed.<sup>73</sup>

The reducing agents Na/Hg,  $[\text{HBEt}_3]^-$ , or Na/K alloy will reduce  $[\{\text{CpMo}(\text{CO})_3\}_2]$  to give the anionic complex  $[\text{CpMo}(\text{CO})_3]^-$ , which can also be prepared through reaction between  $[\text{Mo}(\text{CO})_6]$  and LiCp in THF. Corresponding alkylated cyclopentadiene analogs can also be synthesized in an analogous manner. This anion reacts with a wide range of electrophiles (see *Electrophile*) such as alkyl halides, alkenyl

halides, acyl halides, and other main group element halides to give products of the type  $[\text{CpMo}(\text{CO})_3\text{E}]$ . Protonation of  $[\text{CpMo}(\text{CO})_3]^-$  gives the hydride  $[\text{CpMoH}(\text{CO})_3]$ , which has a  $pK_a$  of 13.9 in acetonitrile.<sup>74</sup>

### 3.3.2 Preparation and Reactivity of $[\text{CpMoX}(\text{CO})_3]$

The halide compounds  $[\text{CpMoX}(\text{CO})_3]$  ( $X = \text{Cl}, \text{Br}, \text{I}$ ) are prepared through treatment of  $[\{\text{CpMo}(\text{CO})_3\}_2]$  with the halogen or through reaction of  $[\text{CpMoH}(\text{CO})_3]$  with a halogenating agent such as  $\text{MeI}$ ,  $\text{CH}_2\text{Br}_2$ , or  $\text{CCl}_4$ . These compounds are good starting materials for the preparation of  $[\text{CpMoX}(\text{L})_n(\text{CO})_{3-n}]$  through simple CO substitution reactions using two-electron donors such as phosphines. Reaction with additional halogen leads to the higher oxidation state compounds  $[\text{CpMoX}_3(\text{CO})_2]$ . The halide ligand can be replaced by alkyl or allyl groups to give compounds of the type  $[\text{CpMoR}(\text{CO})_3]$ . Photolysis of the  $\sigma$ -allyl complex facilitates the  $\sigma$ -to- $\pi$  rearrangement of the allyl ligand, due to dissociation of a carbonyl ligand, affording  $[\text{CpMo}(\text{CO})_2(\eta^3\text{-C}_3\text{H}_5)]$ . Substitution of the halide may also be affected by carbonate anions to give Mo-transition metal bonds. The halide atom may also be abstracted by strong Lewis acids (see *Lewis Acids & Bases*), like  $\text{AgBF}_4$ , in the presence of CO to give the cation  $[\text{CpMo}(\text{CO})_4]^+$  or if the reaction is carried out in the absence of a donor ligand, the  $[\text{BF}_4]^-$  anion may act as a weakly coordinating ligand to give a masked source of the strong Lewis acid  $[\text{CpMo}(\text{CO})_3]^+$  (see *Lewis Acids & Bases*).

### 3.3.3 Monocyclopentadienylhalide Complexes

A slightly dated, but exhaustive, review is available on complexes of the type  $[\text{CpMoX}_n]$ . Cyclopentadienyl halide complexes of molybdenum in the +6 and +2 oxidation states are not known.<sup>75</sup>

***CpMoX<sub>n</sub> and Derivatives.***  $[\text{CpMoX}_4]$  ( $X = \text{Cl}, \text{Br}$ ) are best synthesized by oxidation of  $[\text{CpMoMe}(\text{CO})_3]$  with  $\text{PCl}_5$  or  $\text{PBr}_5$ . The tetrachloride may also be prepared on treatment of  $[\text{CpMoO}(\text{Cl})_2]$  with  $\text{HCl}$ . These  $\text{Mo}^{\text{V}}$  compounds may be reduced to lower valent species. Thus, treatment of  $[\text{CpMoCl}_4]$  with zinc affords the insoluble molybdenum(III) compound  $[(\text{CpMoCl}_2)_n]$ . Enhanced solubility is obtained through the use of alkylated cyclopentadienyl ring systems. The  $\text{Mo}^{\text{IV}}$  complexes are best prepared by one of two methods:

conproportionation of  $[\text{CpMoCl}_4]$  and  $[\text{CpMoCl}_2]$  or by oxidation of  $[\text{CpMoCl}_2]$  with  $\text{PhICl}_2$  and the reactivity of these compounds has been reviewed.<sup>44</sup>

***Cyclopentadienyl Nitrosyl Halides***<sup>76</sup>.  $[\text{CpMoCl}(\text{NO})_2]$  is obtained on treatment of  $[\text{CpMo}(\text{CO})_2(\text{NO})]$  with  $\text{NOCl}$  or from the reaction between  $[\text{CpMoCl}_2]$  and  $\text{NO}$ . Oxidation of  $[\text{CpMo}(\text{CO})_2(\text{NO})]$  with halogens affords the compounds  $[\{\text{CpMoX}_2(\text{NO})\}_2]$ , which contain bridging halides (see *Bridging Ligand*). Subsequent reaction with Grignard reagents gives the corresponding mono and dialkyl complexes with hydrolysis of the latter affording the  $\mu$ -oxo dimer  $[\{\text{CpMoR}(\text{NO})\}_2(\mu\text{-O})]$  (see  *$\mu$ -Oxo Bridge*).

## 3.4 Dicyclopentadienyl Complexes<sup>77,78</sup>

The molybdenum analog of chromocene (see *Metallocene Complexes*)  $[\text{Cp}_2\text{Mo}]$  (molybdenocene) is not stable and has only been isolated using matrix isolation techniques (see *Matrix Isolation*). The IR, magnetic circular dichroism spectra of the matrix isolated  $[\text{Cp}_2\text{Mo}]$  were interpreted in terms of a paramagnetic metallocene, with parallel rings.

The bent metallocenes  $[\text{Cp}_2\text{MoX}_2]$  normally have a  $\text{Cp-Mo-Cp}$  ( $\text{Cp} = \text{ring centroid}$ ) angle near  $130^\circ$ , but the  $\text{X-Mo-X}$  angle depends upon the number of  $d$ -electrons. For  $d^0$  complexes, the angle is approximately  $97^\circ$ , for  $d^1$  it is lowered to  $86$  to  $88^\circ$  and further still to approximately  $82^\circ$  for  $d^2$  systems. These structural features are consistent with the lone pair of  $d^2$  electrons being in an orbital that lies in the  $\text{MoX}_2$  plane with major lobes lying outside the  $\text{MoX}_2$  triangle.

### 3.4.1 Preparation and Reactivity

The dihydride  $[\text{CpMoH}_2]$  was first prepared in 1959 on treatment of  $\text{MoCl}_5$  and  $\text{NaCp}$  in the presence of  $[\text{BH}_4]^-$ , and its chemistry has been extensively developed since then.<sup>77</sup> It behaves as a Lewis base (see *Lewis Acids & Bases*) and is readily protonated to give the cation  $[\text{Cp}_2\text{MoH}_3]^+$ . This cation has been shown to reduce unsaturated organic fragments such as imines, aldehydes, and ketones.<sup>79</sup> Reaction of  $[\text{CpMoH}_2]$  with methyl triflate ( $\text{CH}_3\text{OS}(\text{O})_2\text{CF}_3$ ) gives  $[\text{Cp}_2\text{MoH}\{\text{OS}(\text{O})_2\text{CF}_3\}]$  and  $\text{CH}_4$ . This compound is water-soluble and undergoes hydride deuteride exchange in  $\text{D}_2\text{O}$  and is capable of readily reducing ketones in water under the mild conditions of  $40^\circ\text{C}$  and  $\text{pH } 7$  (see *Organic Synthesis using Transition Metal Complexes Containing  $\pi$ -Bonded Ligands*).<sup>79</sup>  $[\text{Cp}_2\text{MoH}_2]$  also shows its ability to behave as a base by forming adducts with Lewis acids (see *Lewis Acids & Bases*), for example, reaction with  $\text{AgBF}_4$  in the presence of pseudohalide ligands gives the adducts  $[(\text{Cp}_2\text{MoH}_2)_2\text{AgX}]$  ( $X = \text{SCN}^-$ ,  $\text{OCN}^-$ ,  $\text{CN}^-$ , and  $\text{SCF}_3^-$ ). The compound  $[(\text{Cp}_2\text{MoH}_2)_2\text{AgSCN}]$  has been crystallographically characterized and has an average  $\text{Mo-Ag}$  bond length of  $2.963 \text{ \AA}$ .<sup>80</sup> Like the parent compound,

$[\text{Cp}_2\text{MoH}_2]$  substituted cyclopentadienyl ligands can be introduced and the incorporation of alkyl groups onto the Cp ring enhances the complex's solubility in organic solvents. Recently, the compound  $[(^t\text{BuCp})_2\text{MoH}_2]$  (**14**) has been prepared and its chemistry extensively investigated.<sup>61</sup> (**14**) can be converted to  $[(^t\text{BuCp})_2\text{MoX}_2]$  ( $\text{X} = \text{Cl}$  **15**,  $\text{Br}$  **16**) on treatment with  $\text{CCl}_4$  and  $\text{CH}_2\text{Br}_2$  respectively. Reaction with  $\text{MeI}$  gives  $[(^t\text{BuCp})_2\text{MoHI}]$ .

As is generally the case, generation of the dihalides opens up a vast array of chemistry. Thus, treatment of (**15**) with  $\text{RLi}$  or  $\text{RMgX}$  gives the dialkyl complexes  $[(^t\text{BuCp})_2\text{MoR}_2]$  ( $\text{R} = \text{Me}$ ,  $\text{CH}_2\text{Ph}$ ,  $\text{CH}_2\text{SiMe}_3$ ); reaction with  $\text{LiOH}$  gives the oxo-containing complex  $[(^t\text{BuCp})_2\text{Mo}=\text{O}]$ ; reduction with  $\text{Na/Hg}$  in the presence of  $\text{L}$  ( $\text{L} = \text{CO}$ ,  $\text{PMe}_3$ ,  $\text{C}_2\text{H}_4$ ,  $\text{C}_2\text{H}_2$ ,  $\text{NCMe}$ ) gives the formally  $\text{Mo}^{\text{II}}$  adducts  $[(^t\text{BuCp})_2\text{MoL}]$ . Reaction of  $[(^t\text{BuCp})_2\text{Mo}(\text{CO})]$  with elemental  $\text{S}$ ,  $\text{Se}$ , or  $\text{Te}$  gives the compounds  $[(^t\text{BuCp})_2\text{Mo}(\eta^2\text{-E}_2)]$ , where  $\text{E} = \text{S}$  or  $\text{Se}$ ; the compounds have been crystallographically characterized (Figure 11) and both the  $\text{S-S}$  (2.04 Å) and  $\text{Se-Se}$  (2.322 Å) bond lengths are close to those in  $\text{S}_8$  (2.060 Å) and  $\text{Se}_8$  (2.34 Å) suggesting strong back bonding and a  $\text{Mo}^{\text{IV}}$  metallacyclop propane type structure. These reactions mirror those of the parent complex  $[\text{Cp}_2\text{MoCl}_2]$ .

$[\text{Cp}_2\text{MoCl}_2]$  has been shown to hydrolyze phosphoesters under aqueous conditions through the intermediate compound (**16**), which forms from the reaction between  $[\text{Cp}_2\text{Mo}(\text{OH})_2]$ , generated from the hydrolysis of  $[\text{CpMoCl}_2]$ , and the phosphoester.<sup>81</sup> This work has been further developed and the organophosphate pesticides Paraoxon (**17**) and Parathion (**18**) have also been shown to be hydrolyzed by  $[\text{CpMoCl}_2]$  with an enhanced rate.<sup>82</sup>

The compounds  $[(\eta^5\text{-C}_9\text{H}_7)(\text{Cp})\text{MoX}_2]$  ( $\text{C}_9\text{H}_7 = \text{indenyl}$ ) have been prepared and show comparable reaction chemistry to the parent  $[\text{Cp}_2\text{MoX}_2]$  compounds; however, on reduction

(16)

(17)

(18)

a noticeable difference occurs. The ring-slipped products  $[(\eta^3\text{-C}_9\text{H}_7)(\text{Cp})\text{MoL}_2]$  are obtained rather than the expected  $[(\eta^5\text{-C}_9\text{H}_7)(\text{Cp})\text{MoL}]$ . This work has been reviewed<sup>83</sup> and studied theoretically.<sup>84</sup>

### 3.5 Arene-containing Complexes

There are two different general classes of  $\pi$ -bound arene-containing complexes of molybdenum: the monoarene complexes  $[(\eta^6\text{-arene})\text{Mo}(\text{CO})_3]$  or the *bis*-arene complexes  $[(\eta^6\text{-arene})_2\text{Mo}]$ . The solid-state structures of both classes of compound show that the bond lengths around the arene ligand are equivalent. This clearly means that the arene does not bond as a triene through localized electron pairs.

The monoarene complexes can be synthesized directly from  $[\text{Mo}(\text{CO})_6]$ , but the reaction of an arene with  $[\text{Mo}(\text{CO})_3\text{L}_3]$  ( $\text{L} = \text{NCMe}$  or  $\text{py}$  in the presence of  $\text{BF}_3$ ) tend to give better yields and at lower reaction temperatures. The  $\text{Mo}$ -arene bond strength appears to be greater than for the analogous  $\text{Cr}$ -arene ( $280 \text{ kJ mol}^{-1}$  vs  $191 \text{ kJ mol}^{-1}$  (see *Bonding Energetics of Organometallic Compounds*)),<sup>85</sup> however; the molybdenum complexes are thermally less stable and kinetically more labile. The analogous chromium-arene complexes have found much utility in organic synthesis<sup>86</sup> (see *Asymmetric Synthesis by Homogeneous Catalysis* and *Organic Synthesis using Transition Metal Complexes Containing  $\pi$ -Bonded Ligands*), in particular utilizing the planar chirality imposed by  $\pi$ -complexation of the  $[\text{Cr}(\text{CO})_3]$  fragment on one face of the arene ring.<sup>87</sup> The compound  $[\text{Mo}(\text{CO})_3(\eta^6\text{-C}_6\text{H}_3\text{-1,3,5-Bu}_3)]$  and its heteroarene analog  $[\text{Mo}(\text{CO})_3(\eta^6\text{-1,3,5-P}_3\text{C}_3\text{Bu}_3)]$  were both prepared from  $[\text{Mo}(\text{CO})_3(\text{NCMe})_3]$  and studied by Photoelectron Spectroscopy (see *Photoelectron Spectroscopy of Transition Metal Systems*) and Density Functional Theory

**Figure 11** Molecular structure of  $[\text{Mo}(\eta^2\text{-S}_2)(\eta^5\text{-}^t\text{BuCp})_2]$ . (Reproduced by permission of The Royal Society of Chemistry)

(see *Density Functional Theory*). It was found that the 1,3,5-triphenylphosphabenzene ligand is more strongly bound to the molybdenum center because the phosphorus atoms cause a lowering of the energy of the  $\pi$ -acceptor orbitals, and hence allow more  $\pi$ -backbonding and so strengthening the molybdenum arene bond.<sup>88</sup>

The *bis*-arene complexes  $[(\eta^6\text{-arene})_2\text{Mo}]$  can be prepared in two principally different ways. The Fischer–Hafner synthesis: The reaction between  $\text{MoCl}_5$  and an arene in the presence of Al and  $\text{AlCl}_3$ . The problems associated with this method are long reaction times, poor yields, and the limitation on the arenes that may be used. Arenes that have lone pairs such as halobenzenes, anilines, or phenols cannot be used as they form Lewis adducts with  $\text{AlCl}_3$  (see *Lewis Acids & Bases*). Equally, the use of polyalkylated arenes is not possible due to isomerization catalyzed by  $\text{AlCl}_3$ . The parent compound  $[\text{Mo}(\eta^6\text{-C}_6\text{H}_6)_2]$  is green, very air sensitive, and a diamagnetic 18 valence electron species with a melting point of  $115^\circ\text{C}$ .

An alternative synthetic procedure is to use Metal Vapor Synthesis (MVS) (see *Metal Vapor Synthesis of Transition Metal Compounds*). This method of preparation is hindered by the high boiling point of molybdenum and the expense of the MVS apparatus. It does, however, allow a greater range of functionalized *bis*-arene complexes to be synthesized.<sup>89</sup>

*bis*-Heteroarene complexes, like  $[\text{Mo}(\eta^6\text{-C}_5\text{H}_3\text{N-2,6-Me}_2)_2]$ , can also be prepared using this methodology and their reactivity mirrors that of the *bis*-arene molybdenum complexes.<sup>90</sup> The reactivity of  $[\text{Mo}(\eta^6\text{-C}_5\text{H}_3\text{N-2,6-Me}_2)_2]$  is summarized in Scheme 8. The solid-state structure of  $[\{\text{Mo}(\mu\text{-Cl})(\eta^3\text{-C}_3\text{H}_5)(\eta^6\text{-C}_5\text{H}_3\text{N-2,6-Me}_2)\}_2]$  has been determined and shows that the 2,6-lutidine ring is not planar. The nitrogen atom and the *para*-carbon bend in toward the metal center and the two-methyl groups bend away, and differs from the arene systems where the ring remains planar on complexation.

## 4 POLYMETALLIC COMPLEXES

### 4.1 Multiply Bonded Dimers

Molybdenum(II) and molybdenum(III) form an extensive array of multiply bonded dimers, which contain Mo–Mo quadruple and triple bonds respectively.<sup>91</sup> Much of the organometallic chemistry of this class of compound has come principally from the work of one research group.<sup>92</sup> Homoleptic compounds such as  $[\text{Mo}_2\text{Me}_8]^{4-}$ ,  $[\text{Mo}(\eta^n\text{-allyl})_4]$ , which contains bridging and terminal allyl ligands (see *Bridging Ligand*), are readily synthesized from  $[\text{Mo}_2(\text{OAc})_4]$

**Scheme 8** Summary of the reactions of  $[(\eta^6\text{-2,6-Me}_2\text{NC}_5\text{H}_3)_2\text{Mo}]$

on reaction with either MeLi or allyl Grignard respectively. Treatment of  $[\text{Mo}_2(\text{OAc})_4]$  with sources of  $\text{Cp}^-$  does not generate the expected  $\eta^5\text{-Cp}$  coordination rather many compounds that contain bridging  $(\eta^5:\eta^1\text{-})$ cyclopentadienyl ligands and other coupled Cp bound systems (see *Dinuclear Organometallic Cluster Complexes*).

## 4.2 Cluster Compounds

As used here cluster refers to molecules that contain at least 3 metal atoms and electron configurations suitable for the formation of metal–metal bonds. Molybdenum readily forms strong homoleptic metal–metal bonds (see *Homoleptic Compound*) and so it is not surprising that molybdenum is readily incorporated into cluster structures (see *Polynuclear Organometallic Cluster Complexes*).

Early work in this area was often serendipitous but as the field has developed, underpinned concepts such as cluster *Electron Counting* rules and Hoffman's *Isolobal Analogy*, rational cluster syntheses have begun to appear.<sup>93</sup>

## 4.3 Homometallic Complexes

$[\text{M}_3(\text{CO})_{12}]$  ( $\text{M} = \text{Fe}, \text{Ru}$  or  $\text{Os}$ ) are derived formally from  $[\text{M}(\text{CO})_5]$  by replacing 1 of the CO ligands with the formation of 2 metal–metal bonds. However, there are no known analogous molybdenum-centered clusters derived from  $[\text{Mo}(\text{CO})_6]$  in similar fashion. This is likely to be the result of steric congestion (see *Steric Effect*); however, replacement of the CO ligand with smaller groups allows cluster formation as in  $[\{\text{MoH}(\text{CO})_3\}_4]^{4-}$ .

## 4.4 Clusters with Bridging Ligands

Replacement of CO groups with functionalities that are capable of forming bonds between 2 or 3 metal atoms is an effective strategy in cluster synthesis. Good bridging groups include: P, As, S, Se, Te, PR, RS (see *Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements*). There is particular interest in building clusters that contain sulfur due to their potential importance in processes such as hydrodesulfurization processes (see *Hydrodesulfurization & Hydrodenitrogenation*) important in fossil fuel refining. Additional interest is as models of active sites of metalloenzymes such as nitrogenase (see *Metalloprotein Design & Engineering*).<sup>94–96</sup>

Stone's group have been particularly active in the synthesis of molybdenum- and tungsten-centered heteronuclear complexes making effective use of the *Isolobal Analogy* (see *Isolobal Analogy*).<sup>97</sup>

## METHOD SUMMARY

### Acronyms, Synonyms

- Recoilless nuclear resonance absorption of  $\gamma$ -radiation (used by Mößbauer in his Nobel lecture 1961)

### Measured physical quantities

- Mössbauer spectroscopy is a nuclear probe and works best with  $^{57}\text{Fe}$ . Other Mössbauer-active isotopes are, among many others,  $^{61}\text{Ni}$  and  $^{67}\text{Zn}$ .
- In case of  $^{57}\text{Fe}$ , the resonant absorption of 14.4 keV  $\gamma$ -rays emitted by a radioactive  $^{57}\text{Co}$  source is measured. The spectra are determined by the hyperfine interactions (isomer shift, quadrupole splitting, and magnetic hyperfine field) of the Mössbauer nucleus caused by the surrounding electron shell.

### Information available

- spin state as well as oxidation state of the Mössbauer atom
- fine structure parameters like zero-field splitting  $D$  and rhombicity  $E/D$
- hyperfine coupling tensor  $\overleftrightarrow{A}$ , respectively magnetic hyperfine field  $B_{hf}$
- phase transitions in solids
- coordination number and geometry
- dynamic properties: mean-square displacement of the Mössbauer atom, Debye temperature of solids.

### Information not available, limitations

- Coordination number and geometry cannot be determined directly; comparison with model complexes is necessary.
- If several iron species are present in the sample, deconvolution of signals can be tedious.
- Exchange coupling constants  $J$  of polynuclear species can only be estimated, because in addition to  $D$  and  $E/D$ , at least the hyperfine coupling constants of the single sites have to be determined.

**Examples of questions that can be answered**

- Is there high-spin Fe(II) in the sample? What is the ratio of Fe(II) to Fe(III)?
- What are the values of  $D$  and  $E/D$  of a high-spin Fe(II)?
- Is there a  $[2\text{Fe}-2\text{S}]^+$  or a  $[4\text{Fe}-4\text{S}]^{2+}$  center in this protein?

**Major advantages**

- Method “sees” all Mössbauer atoms in the sample and works very well with  $^{57}\text{Fe}$ . There is no Mössbauer-silent  $^{57}\text{Fe}$ .

**Major disadvantages**

- For solution studies, enrichment with  $^{57}\text{Fe}$  is necessary and relatively high  $^{57}\text{Fe}$  concentrations ( $\geq 1\text{ mM}$ ) are needed.

**Sample constraints**

- Sample must be in the solid state: powders, foils, and frozen solutions can be studied. Surface layers can be measured by special techniques (CEMS).
- Sample volume of frozen solutions: typically 0.2–1 mL.
- Thickness of iron foils (not enriched in  $^{57}\text{Fe}$ ): 5–25  $\mu\text{m}$ .

**1 INTRODUCTION**

This article introduces the reader to basic fundamentals and in quite a general way to applications of Mössbauer spectroscopy within inorganic and bioinorganic chemistry. The idea is to allow scientists dealing with metal sites, especially iron chemistry, to decide whether Mössbauer spectroscopy will help in solving their problems. A huge amount of Mössbauer work on almost all iron-containing materials ranging from iron-containing alloys, oxides, ionic as well as coordination compounds<sup>1–6</sup> and metal sites in proteins does exist.<sup>7–11</sup> Mössbauer spectroscopy has also been applied to study nano-sized particles both in solution and heterogeneous catalysts.<sup>12</sup> Special experimental techniques like conversion electron Mössbauer spectroscopy (CEMS) allow us to study surfaces and thin films even down to the monolayer regime.<sup>13,14</sup> The same sensitivity has been reached very recently in experiments on iron monolayers with Mössbauer spectroscopy with synchrotron radiation, also called nuclear forward scattering (NFS) (see *Nuclear Resonance Vibrational Spectroscopy (NRVS)*).<sup>15</sup>

Because of the broad coverage of this article, we will limit ourselves to the study of structural and electronic properties of iron centers by  $^{57}\text{Fe}$  Mössbauer spectroscopy. If the reader is interested in the determination of dynamic properties both by conventional and synchrotron-based Mössbauer spectroscopy, we refer them to the articles by Parak,<sup>16</sup> and Paulsen *et al.*,<sup>17</sup> as well as to the contribution of Scheidt and Sage in this volume (see *Nuclear Resonance Vibrational Spectroscopy (NRVS)*).

**2 TECHNICAL BACKGROUND****2.1 Recoil-free Absorption of  $\gamma$ -Rays**

The term Mössbauer effect describes the recoil-free resonant absorption of  $\gamma$  quanta by nuclei of the same kind as the emitters. If a free nucleus undergoes a transition from an excited state by emission of a  $\gamma$  quantum, it suffers a recoil. The energy of this quantum in the laboratory frame is given as  $E_\gamma^0 = E^0 - E_R$ , where  $E^0$  is the nuclear transition energy and  $E_R$  is the recoil energy of the nucleus after the emission of the  $\gamma$  quantum. It can be expressed as

$$E_R = \frac{E_\gamma^{0^2}}{2Mc^2} \approx \frac{E^{0^2}}{2Mc^2} \quad (1)$$

with  $M$  being the nuclear mass and  $c$  the speed of light. The recoil energy of the nucleus  $E_R$  is approximately  $10^6$  larger than the energy width  $\Gamma$  of the excited nuclear state. Thus the lifetime broadening of the nuclear transition cannot exceed the recoil energy and therefore resonance absorption of  $\gamma$  quanta emitted by free nuclei is not possible.

Rudolf Mössbauer found during work on his PhD thesis in 1953 that, if  $^{191}\text{Ir}$  nuclei are embedded in a crystal lattice, there is a certain probability for recoil-free emission and absorption of  $\gamma$  quanta.<sup>18</sup> Later he received the Nobel prize because in the meantime it had been found that recoil-free emission and absorption of  $\gamma$  quanta also worked for  $^{57}\text{Fe}$  and this boosted the application of the technique in physics, material science, and chemistry. A very instructive description of these investigations can be found in his Nobel lecture.<sup>19</sup>

Qualitatively the effect can be explained by a simple picture: the recoil energy of a single nucleus is taken up by the whole lattice and the expression for the recoil energy (equation 1) does not contain the mass  $M$  of the nucleus anymore, but contains the mass of the whole lattice  $M_{\text{lattice}}$ :

$$E_R^{\text{Moss}} = \frac{E^2}{2M_{\text{lattice}}c^2} \cong 0 \quad (2)$$

Because  $M_{\text{lattice}}$  is much larger than the nuclear mass  $M$ , the recoil energy is negligible and resonance absorption takes place. In terms of quantum mechanics, there is a probability  $f$  for a zero-phonon process, where no lattice vibrations are excited. Rudolf Mössbauer showed that the probability  $f$  for a zero-phonon process is given by the subsequently named Lamb–Mössbauer factor:

$$f = \exp\{-k^2 \langle x^2 \rangle\} \quad (3)$$

The quantity  $\langle x^2 \rangle$  denotes the mean-square displacement of the Mössbauer nucleus in the direction of the incoming  $\gamma$ -ray and  $k = 2\pi/\lambda$  is the wave number of the  $\gamma$ -ray. The decrease of the mean-square displacement  $\langle x^2 \rangle$  with decreasing temperature leads to an increase of the Lamb–Mössbauer factor  $f$  and thus the Mössbauer effect.

## 2.2 Experimental Setup and Spectral Line Shape

### 2.2.1 Transmission Geometry

A setup in transmission geometry is the standard implementation of  $^{57}\text{Fe}$  Mössbauer spectroscopy. In a transmission experiment, the  $\gamma$ -rays emitted by the radioactive source are registered by a detector after they have passed the absorber. This method works with powders, foils, and frozen solutions. In order to investigate the energy spectrum of the absorber nuclei, the energy of the emitted  $\gamma$ -ray is modulated by moving the source relative to the absorber with a velocity  $V$  according to  $E_\gamma = (1 + \frac{V}{c}) E_{\text{source}}^0$ . The source is mounted on the Mössbauer drive, which is basically a loudspeaker driven either by a sinusoidal or triangular shaped current (Figure 1).

The magnitude of the observed Mössbauer effect is determined by the effective thickness of the absorber, which is a dimensionless quantity given by

$$t_{\text{eff}} = f \sigma_0 N_A \beta \rho \frac{\Delta x}{A} \quad (4)$$

with  $f$  being the Lamb–Mössbauer factor and  $\sigma_0$  denoting the resonance cross section for absorption of  $\gamma$  quanta.  $N_A$  is the Avogadro constant,  $\beta$  is the relative isotopic abundance of the Mössbauer-active element in the absorber,  $\rho$  is the mass density of the sample,  $\Delta x$  is the geometric thickness of the absorber, and  $A$  is the molar mass of the Mössbauer isotope.

**Figure 1** Mössbauer spectrometer with velocity calibrator Mössbauer drive and detector. The sample is placed between drive and detector. For measurements at cryogenic temperatures, the sample is mounted in a cryostat equipped with Mylar or beryllium windows. (Reproduced with permission Wissel GmbH)

The transmission through an absorber of thickness  $t_{\text{eff}}$  as a function of the relative velocity  $V$  between source and absorber is given by the evaluation of the transmission integral discussed, for example, in Ref. 2. In case of  $^{57}\text{Fe}$  Mössbauer spectroscopy for almost all samples which are not enriched in the Mössbauer isotope  $^{57}\text{Fe}$  (the natural abundance of  $^{57}\text{Fe}$  is 2%), the evaluation of the transmission integral leads to Lorentzian line shape with a minimum linewidth of  $0.19 \text{ mm s}^{-1}$ , which is twice the natural linewidth of the  $^{57}\text{Fe}$  Mössbauer transition. The absorption cross section as a function of source velocity is then given as (with  $\sigma_0 = 2.56 \cdot 10^{-18} \text{ cm}^2$  for  $^{57}\text{Fe}$ )

$$\sigma(V) = \frac{\Gamma^2/4}{(V - V_{\text{res}})^2 + (\Gamma/2)^2} \sigma_0 \quad (5)$$

### 2.2.2 Backscattering Geometry

This technique measures the radiation emitted by the sample after the excited Mössbauer nuclei have returned to their ground state. Backscattered radiation consists of X rays originating from the electron shell,  $\gamma$ -rays from the nucleus, or conversion electrons. Since self absorption prevents  $\gamma$  or X rays from escaping from the inner part of the sample, only a layer at the surface contributes to the backscattered spectrum. The thickness of this layer depends on the energy range and the kind of detected radiation. If one detects  $\gamma$  and/or X rays in backscattering geometry, the escape depth is approximately  $10^{-6} \text{ m}$  for  $^{57}\text{Fe}$  Mössbauer spectroscopy. It is also possible to detect conversion electrons, and in this case the surface layer is even smaller and one can reach monolayer sensitivity. This technique is called *conversion electron Mössbauer spectroscopy* (CEMS). By detecting the

electrons in an energy dispersive fashion, Mössbauer spectra from surface layers of varying thickness can be obtained.

Although chemical and biological samples are routinely measured in transmission geometry, the detection of backscattered Mössbauer radiation may also be considered when thin films of bioinorganic complexes or samples that cannot be moved to a laboratory should be studied. The group of G. Klingelhöfer has designed such a transportable miniaturized Mössbauer spectrometer (MIMOS), which contains all necessary mechanical and electronic parts (including a Mössbauer drive and radiation detector) in a box that can be held in one hand (Figure 2). This spectrometer has even been used to perform Mössbauer measurements on the planet Mars.<sup>20,21</sup> Other applications of this spectrometer, which is commercially available, are, for example, the destruction-free examination of artwork and field studies of soil.

### 2.2.3 Sample Requirements and Pitfalls during Sample Preparation

Metallic foils can be conveniently measured in absorption geometry. An  $\alpha$ -Fe foil of 25  $\mu\text{m}$  thickness and an area of  $\sim 1\text{ cm}^2$  is often used as a calibration standard. With such a foil and using a  $^{57}\text{Co}$  source with an activity of  $\sim 50\text{ mCi}$ , it is possible to acquire a decent spectrum at room temperature in less than 1 h.

Powder samples of inorganic iron compounds can be conveniently measured with sample holders that have a sample thickness of  $\sim 0.5\text{ mm}$  and an area of  $\sim 1\text{ cm}^2$ . This makes a total sample volume of  $\sim 50\text{ }\mu\text{L}$ . Some Mössbauer groups prefer to measure pressed pellets, but this decision depends often on history and individual laboratory habits. If sample holders like those displayed in Figure 3 are used, one has to take special care that there are no holes in the sample. This would mean that the  $\gamma$ -rays go through the sample holder

**Figure 2** The Mars Exploration Rover Spirit's Mössbauer spectrometer. The hydroxyl containing mineral goethite ( $\text{FeOOH}$ ) has been identified with this spectrometer in the "Columbia Hills" of Mars. This finding produced strong evidence for past water activity in the area that Spirit has been exploring.<sup>22</sup> (Reproduced from web page with permission G Klingelhöfer)

**Figure 3** Sample holders made of Delrin<sup>®</sup> for Mössbauer spectroscopy of powders (left) and frozen solutions (right). The measurement rule has units of centimeters

but do not penetrate sample material and can lead to a drastic decrease in the intensity of the Mössbauer lines. A simple test is to check whether light is shining through the sample holder. This is especially important when only a tiny amount of sample is present. In such a case, it also helps to put a thin sheet of paper in between the sample holder and the sample. If the sample holder is prepared correctly, it is possible that there is only a very weak Mössbauer spectrum at room temperature. In this case, the Mössbauer–Lamb factor  $f$  is small and therefore it is advisory to measure at cryogenic temperatures  $\leq 120\text{ K}$ . The experience in our laboratory is that measuring a powder sample of an iron compound with an atomic mass of around 500–1000 amu at 77 K in a sample holder made of Delrin<sup>®</sup>, like those displayed in Figure 3, normally takes not more than 24 h.

For liquid solutions containing iron compounds or proteins, the Mössbauer–Lamb factor goes to zero, and therefore  $^{57}\text{Fe}$  Mössbauer spectroscopy on solutions is only possible in the frozen state. Since the natural abundance of  $^{57}\text{Fe}$  is only 2%, it is advisable to perform Mössbauer studies on solutions with  $^{57}\text{Fe}$ -enriched samples. For protein studies,  $^{57}\text{Fe}$  enrichment is essential. Typical sample volumes can range from 0.25–1.0 mL. In some cases, frozen solution studies can be performed down to an  $^{57}\text{Fe}$  concentration of  $\sim 0.1\text{ mM}$ , but taking a Mössbauer spectrum of such a sample can take weeks depending on the shape of the spectrum and the outcome is uncertain. Therefore, it is strongly recommended that the concentration of  $^{57}\text{Fe}$  be at least 1 mM. Samples with  $^{57}\text{Fe}$  concentrations of, for example, 10 mM can very conveniently be measured in a couple of hours—such samples the Mössbauer spectroscopists like the most. In any case, for

$^{57}\text{Fe}$ -enriched iron proteins a general rule exists: the higher the protein concentration the better.

## 2.3 Hyperfine Structure of $^{57}\text{Fe}$ Mössbauer Spectra

Mössbauer spectroscopy senses the hyperfine interactions, which are present at the nucleus of the Mössbauer isotope. The electrical monopole interaction causes the isomer shift and the electric quadrupole interaction leads to the quadrupole splitting, which in the case of  $^{57}\text{Fe}$  causes a two-line Mössbauer pattern. The magnetic dipole interaction leads to a magnetically split six-line pattern (Figure 4). In the following text, these interactions and their deduction from Mössbauer spectra will be discussed.

### 2.3.1 The Isomer Shift $\delta$

The electric monopole interaction is proportional to the s-electron density at the iron nucleus  $|\varphi(0)|^2$  and can be expressed by

$$E = \frac{2}{3}\pi \cdot Z^2 e^2 |\varphi(0)|^2 \cdot \langle r^2 \rangle \quad (6)$$

with  $\langle r^2 \rangle$  being the mean-square nuclear radius and  $Ze$  being the nuclear charge. In general, source and absorber nuclei are embedded in different matrices, which leads to different s-electron densities at the source and the absorber nuclei. As a consequence, the energy of the Mössbauer nuclei in the source and in the absorber have slightly different energy

**Figure 4** (a) Decay scheme of  $^{57}\text{Co}$ . The 14.4-keV transition used for  $^{57}\text{Fe}$  Mössbauer spectroscopy is shown in red. (b) Mössbauer transitions without magnetic field. (c) Mössbauer spectrum with quadrupole doublet. (d) Energy levels of the  $^{57}\text{Fe}$  states and Mössbauer transitions in the presence of a magnetic field. (e) Magnetic Mössbauer spectra for different orientations of the magnetic field relative to the propagation direction of  $\gamma$ -ray. The quadrupole interaction has been neglected in (d) and (e). (Reprinted with permission from Krebs, Price, Baldwin, Saleh, Green and Bollinger.<sup>23</sup> © 2005 American Chemical Society)

shifts of  $\delta E_{\text{source}}$  and  $\delta E_{\text{absorber}}$ . Therefore, the isomer shift  $\delta$  is expressed as

$$\delta = \delta E_{\text{source}} - \delta E_{\text{absorber}} \quad (7)$$

For a homogenous charge distribution, the isomer shift is given as

$$\delta = \frac{4}{5} \pi Z e^2 R^2 \frac{\delta R}{R} [|\varphi(0)_{\text{absorber}}|^2 - |\varphi(0)_{\text{source}}|^2] \quad (8)$$

with  $R = \frac{1}{2}(R_e + R_g)$  and  $\delta R = R_e - R_g$ , where  $R_g$  and  $R_e$  are the nuclear radii of the ground and excited state, respectively.

For iron,  $\delta R = R_e - R_g$  is negative and therefore a more positive isomer shift implies a lower value of  $|\varphi(0)_{\text{absorber}}|^2$ . This may be caused either from a decrease in the total s-electron population or from shielding of s electrons by the 3d electrons. The isomer shift is sensitive to the oxidation state of the iron and typical values against metallic iron at 300 K are given in Figure 5.

The experimentally observed isomer shift can be expressed as a sum of the temperature-independent term  $\delta_0$  and the temperature-dependent second-order Doppler shift

$\delta_{\text{SOD}}$

$$\delta = \delta_0 + \delta_{\text{SOD}} \quad \text{with} \quad \delta_{\text{SOD}} = -\frac{E_\gamma \langle v^2 \rangle}{2c^2} \quad (9)$$

with  $\langle v^2 \rangle$  denoting the mean-square velocity of the iron atom and  $c$  denoting the speed of light.

### 2.3.2 The Electric Quadrupole Splitting $\Delta E_Q$

The electric quadrupole interaction is described by the Hamiltonian

$$\hat{H}(E2) = \frac{eQV_{zz}}{4I(2I-1)} [3\hat{I}_z^2 - I(I+1) + \eta(\hat{I}_x^2 - \hat{I}_y^2)] \quad (10)$$

with  $Q$  being the nuclear quadrupole moment and  $I$  being the nuclear spin of the nuclear state.  $\hat{I}_x^2$ ,  $\hat{I}_y^2$ , and  $\hat{I}_z^2$  being the corresponding spin operators. The coordinate frame of the electric field gradient (EFG) tensor  $\vec{V}$  is conventionally chosen in such a way that  $|V_{xx}| \leq |V_{yy}| \leq |V_{zz}|$ . The asymmetry parameter  $\eta$  is generally defined as

$$\eta = \frac{V_{xx} - V_{yy}}{V_{zz}} \quad (11)$$

Since the electric quadrupole moment of the nuclear ground state of iron  $^{57}\text{Fe}$  with  $I_g = 1/2$  is zero, the quadrupole interaction does not affect the ground state, but splits the first excited nuclear state with  $I_e = 3/2$  into two sublevels. As a result, it produces, in the case of  $^{57}\text{Fe}$ , a two-line Mössbauer absorption pattern (Figure 4) with a corresponding quadrupole splitting  $\Delta E_Q$  given by

$$\Delta E_Q = \frac{1}{2} eQV_{zz} \sqrt{1 + \frac{\eta^2}{3}} \quad (12)$$

The largest component of the EFG tensor  $V_{zz}$  and the asymmetry parameter  $\eta$  can only be determined separately when a magnetic interaction is present in addition. They reflect the population of the iron 3d orbitals as well as the ligand charges surrounding the iron. For a more detailed description, see Ref. 2 as well as a review on iron porphyrins by Debrunner.<sup>24</sup>

### 2.3.3 The Magnetic Splitting $B_{\text{hf}}$

The third term of the nuclear Hamiltonian contains two contributions. The nuclear Zeeman term couples the magnetic moment of the nucleus to the external magnetic field  $\vec{B}_0$ . Furthermore, there is a term that describes the interaction of the nuclear spin with the internal magnetic hyperfine field. For paramagnetic samples this is often done in terms of the hyperfine coupling tensor  $\vec{A}$ , which multiplied by the spin

**Figure 5** Ranges of isomer shifts observed in various oxidation and spin states of iron (given relative to  $\alpha$ -iron at 300 K). Shadowing indicates the most frequently observed configurations. (From Greenwood and Gibb.<sup>3</sup> With kind permission from Springer Science & Business Media)

expectation value  $\langle \vec{S} \rangle$  of the corresponding electronic state of, for example, the iron ion, that produces the internal magnetic hyperfine field

$$\vec{B}_{\text{hf}} = -\langle \vec{S} \rangle \cdot \vec{A} / (g_N \mu_N) \quad (13)$$

Therefore the hyperfine coupling  $\vec{A}$  tensor is often given in units of Tesla ( $\vec{A} / g_N \mu_N$ ; 1 T  $\hat{=}$  1.36 MHz for  $^{57}\text{Fe}$ ). The magnetic Hamiltonian is given as

$$\hat{H}(M1) = \langle \vec{S} \rangle \cdot \vec{A} \cdot \vec{I} - g_N \mu_N \vec{B}_0 \cdot \vec{I} = -g_N \mu_N (\vec{B}_{\text{hf}} + \vec{B}_0) \cdot \vec{I} \quad (14)$$

where  $g_N$  is the nuclear  $g$  factor and  $\mu_N$  is the nuclear magneton. If the internal hyperfine field is zero as is the case of diamagnetic ions, the energy eigenvalues of a nuclear spin  $I$  in a magnetic field  $B_0$  are given as

$$E_M(m) = -m g_N \mu_N B_0 \quad (15)$$

This leads to the energy differences between nuclear ground and excited state

$$\Delta E_M(m_e; m_g) = B_0 (m_e g_N^e \mu_N - m_g g_N^g \mu_N) \quad (16)$$

For  $^{57}\text{Fe}$  with a ground state nuclear spin of  $I_g = 1/2$  and  $I_e = 3/2$  for the excited state and taking into account the dipole selection rules  $\Delta M = 0, \pm 1$ , one gets six transitions of different energy, which means a six-line pattern as shown in Figure 4.

For most cases, the internal field is much higher than the external magnetic fields. Metallic iron for example exhibits a magnetic hyperfine field ( $-33$  T at 300 K) that is oriented opposite to the magnetization of the sample. The internal hyperfine field contains particularly valuable information about the electronic configuration of the iron atom and is determined by four contributions:

$$\vec{B}_{\text{hf}} = \vec{B}_{\text{fc}} + \vec{B}_{\text{ls}} + \vec{B}_{\text{dd}} + \vec{B}_{\text{latt}} \quad (17)$$

$\vec{B}_{\text{fc}}$  is due to the Fermi-contact interaction, which is caused by the core polarization of the s-electron density at the nucleus. The sign of  $\vec{B}_{\text{fc}}$  is negative, which can qualitatively be rationalized in the following way: in the case of iron, the unpaired 3d electrons attract the spin parallel s electrons via exchange interaction. This leaves an excess of antiparallel s-electron spin density at the nucleus, which leads to the negative sign of  $\vec{B}_{\text{fc}}$ .  $\vec{B}_{\text{fc}}$  dominates, for instance, in high-spin ferric Fe(III), whereas low-spin ferric iron shows a considerable contribution of  $\vec{B}_{\text{ls}}$  due to spin-orbit interaction. The dipole field  $\vec{B}_{\text{dd}}$  originating from the electron shell as well as lattice contributions  $\vec{B}_{\text{latt}}$  are normally of the order of 1 T and therefore negligible in most cases.

### 2.3.4 The Spin Hamiltonian Formalism: Determination of Zero-Field Splitting $D$ and Rhombicity $E/D$ of Paramagnetic Iron Centers by Mössbauer Spectroscopy

Mössbauer spectroscopy can also be used to obtain information about fine structure parameters like zero-field splitting  $D$  and rhombicity parameter  $E/D$ . The zero-field splitting is a second-order effect, which can be classically visualized as resulting from the circular currents generated in the atomic shell by the electron spin. In Section 3.10.5, we describe how  $D$  and  $E/D$  can be calculated.

The spin Hamiltonian formalism, which is also needed to interpret, for example, electron paramagnetic resonance or magnetic circular dichroism spectra (see *Magnetic Circular Dichroism (MCD) Spectroscopy*), was first applied to the interpretation of magnetic Mössbauer spectra by Wickmann, Klein and Shirley<sup>25</sup> and was implemented into a computer program by Münck *et al.* in the early 1970s.<sup>26</sup> For most studies of mononuclear iron centers with electron spin quantum number  $S$ , the following electronic Hamiltonian is used:

$$\hat{H}_{\text{fs}} = D \left[ \hat{S}_z^2 - \frac{1}{3} S(S+1) + \frac{E}{D} (\hat{S}_x^2 - \hat{S}_y^2) \right] + \mu_B \vec{S} \cdot \vec{g} \cdot \vec{B} \quad (18)$$

Here  $\hat{S}_x^2$ ,  $\hat{S}_y^2$ ,  $\hat{S}_z^2$ , and  $\vec{S}$  are the corresponding quantum mechanical spin operators,  $\vec{B}$  is the external magnetic field, and  $\vec{g}$  denotes the electronic  $g$  tensor. After diagonalization of equation (18) in the spin space, the spin expectation values  $\langle \vec{S}_i \rangle$  can be calculated for every fine structure sublevel  $i$ . The fine structure levels are separated by energy gaps, which are a function of  $D$ ,  $E/D$ , and the external field  $\vec{B}$ . The energy gaps between the fine structure sublevels are of the order of some wave numbers. According to equation (13), the spin expectation values  $\langle \vec{S}_i \rangle$  lead to a characteristic magnetic hyperfine field  $B_{\text{hf}}$  at the iron nucleus, which manifests itself in a magnetic splitting of the spectrum. In order to simulate spectra of frozen solutions or powder samples by the spin Hamiltonian formalism, spectra for all orientations of the molecule with respect to the external field have to be calculated and summed up (powder average). Details of this procedure will not be discussed here, but can be found in Refs. 7, 8, 11, and 24. Nowadays several program packages are available. We are using the package VINDA, which runs under Windows environments and is available free of charge via the web site of Palle Gunnlaugson.<sup>27</sup> While working at the laboratory of Prof. Alfred X. Trautwein, Dr. Gunnlaugson had included the code that had been used at that time in the Trautwein group in VINDA. Some Mössbauer groups use the package WMOSS, which is distributed by Web Research Co.,<sup>28</sup> and others use their own codes. Unfortunately, the broadly used software package NORMOS does not have the option to evaluate paramagnetic Mössbauer spectra by full diagonalization of the

spin Hamiltonian matrix to date, but this might be included in the future.

### 3 APPLICATIONS

#### 3.1 Metallic Iron, Iron Nanoparticles, and Thin Films

##### 3.1.1 Metallic Iron

The Mössbauer spectrum of metallic  $\alpha$ -iron at room temperature is used as a velocity calibration standard in almost every Mössbauer laboratory. Therefore most isomer shift values published to date are given relative to metallic iron at room temperature.<sup>a</sup> The ferromagnetism of  $\alpha$ -Fe is caused by unpaired spin density in its electronic band structure. The unpaired electronic spin density is able to couple to the nucleus via magnetic hyperfine interactions. This leads to a magnetic six-line pattern which reflects a very high magnetic hyperfine field of  $B_{\text{hf}} = -33$  T at the iron nucleus. In the case of metallic iron and iron-containing alloys as well as minerals, the interaction between electron spin  $\vec{S}$  and nuclear spin  $\vec{I}$  proceeds predominantly via isotropic Fermi-contact interaction. Therefore, the magnetic hyperfine field at the iron nucleus  $B_{\text{hf}}$  is proportional to the magnetization of the sample and temperature-dependent measurements of  $B_{\text{hf}}$  can be regarded as complementary to magnetization measurements. The determination of the temperature dependence of the magnetic hyperfine field of  $\alpha$ -Fe and its saturation magnetization (Figure 6) was one of the very first applications of  $^{57}\text{Fe}$ -Mössbauer spectroscopy.

**Figure 6** Temperature dependence of the magnetic hyperfine field  $B_{\text{hf}}(T)$  of  $\alpha$ -Fe as a function of  $T/T_c$  with  $T_c$  being the Curie Temperature. Note that  $B_{\text{hf}}(T)$  is scaled with the value extrapolated to 0 K which is denoted as  $B_{\text{hf}}(0)$ . The dots represent Mössbauer data and the solid line represents saturation magnetization data. (Redrawn after Greenwood and Gibb.<sup>3</sup> With kind permission from Springer Science & Business Media)

Figure 6 shows that the magnetic hyperfine field does indeed scale very nicely with data from magnetic measurements. It should be noted that such measurements can be performed on any magnetic material to investigate magnetic phase transitions no matter whether the iron atom is present in an alloy, in an oxide or as an impurity in normally non-iron-containing materials. This is always true if the Fermi-contact interaction is the dominant contribution to the magnetic hyperfine field, which holds for metallic iron and ferric high-spin iron having  $S = 5/2$ .

##### 3.1.2 Iron Nanoparticles

If the dimension of a metallic  $\alpha$ -Fe-particle (or any ferro-, antiferro-, or ferrimagnetic material) reaches the dimensions of magnetic domains, the particle turns into a single-domain particle. Owing to thermal excitation, the magnetization of the single-domain particle can relax between the axes of easy magnetization. Such a magnetic behavior of small single-domain particles is called *superparamagnetic*. If the relaxation rate of a superparamagnetic particle is fast with respect to the lifetime of the excited state of the  $^{57}\text{Fe}$  nucleus ( $\sim 10^{-7}$  s), the nucleus sees on average no magnetic field and only a quadrupole doublet occurs.<sup>12</sup> This is often the case if small nanoparticles of metallic iron or iron oxides are measured at room temperature. In order to unambiguously identify the magnetic phase of these systems, measurements at cryogenic temperatures are helpful. By lowering the temperature, the relaxation rate of the superparamagnetic particles is slowed down and a magnetically split pattern occurs (Figure 7).<sup>29</sup>

In the simplest case of uniaxial relaxation, a relaxation process where the magnetization flips around an angle of  $180^\circ$ , the relaxation rate of a single-domain particle with the saturation magnetic moment  $\vec{\mu}$  in a magnetic field  $\vec{B}$  at a given temperature  $T$  is expressed as

$$\nu = \nu_0 \cdot \exp\left(-\frac{KV + \vec{\mu} \cdot \vec{B}}{k_B T}\right) \quad (19)$$

The energy barrier  $E_a = KV$  is called the *anisotropy energy* and describes the strength of the pinning of the single-domain particle magnetization. The anisotropy energy  $KV$  can be determined by analyzing temperature-dependent Mössbauer measurements in zero magnetic field with suitable relaxation models (Figure 8).<sup>30</sup> A simpler approach is the determination of the superparamagnetic blocking temperature  $T_B$ . For this temperature one assumes  $k_B T_B \cong KV$ . By definition the blocking temperature of an ensemble of superparamagnetic particles is the temperature where half of the spectral area of the Mössbauer spectrum shows magnetic splitting and the other half of the spectrum shows a doublet or a single line depending on the size of the quadrupole splitting. An approach to determine  $T_B$  is to fit the temperature-dependent spectra with at least two components: a simple quadrupole doublet with Lorentzian line shape and a spectrum

**Figure 7** Mössbauer spectrum of nanometer-sized metallic iron particles in zeolite NaX obtained at  $T = 4.2$  K before (A) and after (B) subtraction of two Fe(II) contributions with  $\delta_1 = 0.75$  mm s<sup>-1</sup> and  $\Delta E_{Q1} = 0.8$  mm s<sup>-1</sup> (5% relative contribution) and  $\delta_2 = 0.85$  mm s<sup>-1</sup> and  $\Delta E_{Q2} = 1.85$  mm s<sup>-1</sup> (6% relative contribution). The analysis of the magnetic hyperfine field distribution identifies metallic  $\alpha$ -Fe-nanoparticles. (From Schünemann, Winkler, Butzlaff and Trautwein.<sup>29</sup> With kind permission from Springer Science & Business Media)

**Figure 8** Temperature-dependent Mössbauer spectra of metallic iron nanoparticles in zeolite NaX (a). The superparamagnetic blocking temperature  $T_c$  is around 40 K. The solid lines have been calculated by a relaxation formalism<sup>30</sup> assuming a hyperfine field distribution as shown in (b) with a bimodal size distribution of metallic iron particles. (Reprinted from Schünemann, Winkler, Butzlaff and Trautwein.<sup>29</sup> With kind permission from Springer Science & Business Media)

generated by a hyperfine field distribution that represents the magnetically blocked particles. Fitting of Mössbauer spectra with hyperfine field distributions has been pioneered by Le Caer *et al.*<sup>31</sup> Nowadays the software packages NORMOS and VINDA allow us to calculate hyperfine field distributions.<sup>27</sup>

As an example, temperature-dependent Mössbauer spectra of nanometer-sized metallic iron particles prepared by thermal decomposition of Fe(CO)<sub>5</sub> on a zeolitic support are shown in Figure 8(a). The analysis of the 4.2 K spectrum by a distribution of hyperfine fields (Figure 7) according to the method of Le Caer *et al.*<sup>31</sup> shows that 90% of the iron is in a magnetically ordered state, with the maximum of the distribution corresponding to metallic iron, whereas 10% remained paramagnetic Fe(II). The spectra could be simulated by an algorithm for uniaxial relaxation<sup>30</sup> assuming two particle fractions with different anisotropy energies and different isomer shifts (0.1 and 0.25 mm s<sup>-1</sup> at 4.2 K for the larger and smaller particle fraction, respectively) but with the same hyperfine field distribution (Figure 8b). This analysis has been motivated by ferromagnetic resonance results.<sup>32</sup> The anisotropy energies  $E_{ai} = K_i V_i$  ( $i = 1, 2$ ) were determined from the temperature-dependent relaxation rates  $\nu(T)$  by assuming the Neel equation (equation 19). Values of  $(2.7 \pm 0.4) \cdot 10^{-22}$  J and  $(9.8 \pm 1.5) \cdot 10^{-22}$  J were obtained. Using the values of  $K_1 = (1.45 \pm 0.2) \cdot 10^5$  J m<sup>-3</sup> and  $K_2 = (1.21 \pm 0.18) \cdot 10^5$  J m<sup>-3</sup> obtained from ferromagnetic resonance measurements one obtains, under the assumption that the particles are spherical and have the saturation magnetization of the bulk  $\alpha$ -Fe, the diameters of  $d_1 = (1.53 \pm 0.15)$  nm and  $d_2 = (2.50 \pm 0.25)$  nm. Obviously, one fraction of particles is in the large zeolite cavities, which have a diameter of 1.3 nm. The other fraction of particles is located in defect sites of the zeolite lattice and/or on the surface of the microcrystalline zeolite support.

Another very elegant method to determine the magnetic moment  $\mu$  of superparamagnetic particles involves Mössbauer spectroscopic measurements above the blocking temperature  $T_c$  in varying external magnetic fields, a method that had been first introduced by Steen Morup.<sup>12</sup> In this case, the magnetic energy of the particles  $\mu B$  is much larger than the anisotropy energy, so  $\mu B \gg K V$  holds. The observed magnetic hyperfine field  $\vec{B}_{\text{obs}}$  at the iron nucleus is expressed as

$$\vec{B}_{\text{obs}} = \vec{B}_0 L\left(\frac{\mu B}{k_B T}\right) + \vec{B} \quad (20)$$

Here  $\vec{B}_0$  is the saturation hyperfine field,  $L$  is the Langevin function, and  $k_B$  is the Boltzmann constant. If the condition  $\mu B/k_B T \gg 1$  is fulfilled (e.g., for particles having particle magnetizations of 1000–10 000  $\mu_B$  and external fields  $B$  on the order of 1 T as well as temperatures around 80 K),

equation (20) simplifies to

$$|\vec{B}_{\text{obs}} - \vec{B}| = B_0 \left(1 - \frac{k_B T}{\mu B}\right) \quad (21)$$

Figure 9 shows a plot of  $|\vec{B}_{\text{obs}} - \vec{B}|$  against  $1/B$  for metallic  $\alpha$ -Fe particles in zeolite NaX.<sup>32</sup> From the slope of the curve, a mean magnetic moment of  $\mu = 916 \pm 180 \mu_B$  has been obtained. With the saturation magnetization of  $\alpha$ -Fe and assuming spherical particle sizes with body-centered cubic structure, one obtains a mean diameter of  $d = 2.1 \pm 0.1$  nm.

### 3.1.3 Thin Films

Some bioinorganic chemists may also be interested in the characterization of bioinorganic or inorganic complexes on surfaces or in thin films. Such studies are rare to date, but we refer to reviews by Shinjo and Przybylski, which deal with the characterization of iron monolayers and multilayers by CEMS.<sup>13,14</sup> During the last two decades Mössbauer spectroscopy with synchrotron radiation has also been developed, which gives information about the magnetization of thin iron films with a sensitivity down to the monolayer range.<sup>15</sup>

## 3.2 Covalent Iron Compounds

Iron organometallic compounds are diamagnetic and highly covalent. The parent compounds of this class of molecular compounds are Fe(CO)<sub>5</sub> and the cyclopentadienyl complex ferrocene ( $\pi$ -C<sub>5</sub>H<sub>5</sub>)<sub>2</sub>Fe. Since no internal hyperfine field is present owing to the diamagnetism of the compounds, indications of the type of stereochemistry and bonding can be inferred only from their isomer shifts and quadrupole splittings. Their isomer shifts range from  $-0.18$  mm s<sup>-1</sup> to  $+0.54$  mm s<sup>-1</sup> and the quadrupole splittings from 0 up to  $2.8$  mm s<sup>-1</sup>.<sup>3</sup>

Since iron carbonyls are not only involved in chemical synthesis (of e.g., iron nanoparticles) but also can occur in heterogeneous iron catalysts during reaction conditions (e.g., Fischer–Tropsch reactions), we will briefly discuss the Mössbauer parameters of this class of compounds.

Iron pentacarbonyl has  $\delta = -0.35$  mm s<sup>-1</sup>, which reflects the strong covalency of the Fe–CO bonds. The high value of the quadrupole splitting ( $\Delta E_Q = 2.57$  mm s<sup>-1</sup>) is explained by the noncubic iron site geometry. The Fe(CO)<sub>4</sub><sup>2-</sup> anion has a perfect tetrahedral coordination of CO and therefore no detectable quadrupole splitting is observed in Na<sub>2</sub>[Fe(CO)<sub>4</sub>]. The isomer shift of this compound is  $\delta = -0.45$  mm s<sup>-1</sup>, which reflects the empirical rule that decreasing the coordination number of the iron center by one leads to a decrease of the isomer shift by  $\Delta\delta \approx 0.1$  mm s<sup>-1</sup>. Fe<sub>2</sub>(CO)<sub>9</sub> has axial symmetry with three bridging CO groups and an Fe–Fe bond. The two iron sites are equivalent and

**Figure 9** Mössbauer spectra of metallic iron nanoparticles in zeolite NaX taken at  $T = 77$  K and different external fields (a). The analysis of the field dependence of the magnetic hyperfine field according to equation (21) yields a mean particle size of  $d = 2.1 \pm 0.1$  nm (b). (Reprinted from Schünemann<sup>32</sup>)

**Table 1** Isomer shifts  $\delta$  and quadrupole splittings  $\Delta E_Q$  of some selected iron carbonyls. These compounds are diamagnetic and therefore do not have an internal magnetic hyperfine field. (From Greenwood and Gibb.<sup>3</sup> With kind permission from Springer Science & Business Media)

| Compound                               | $\delta$ [mm s <sup>-1</sup> ] | $\Delta E_Q$ [mm s <sup>-1</sup> ] |

|                                        | -0.21                          | 0.13(33%)                          |
| Na <sub>2</sub> [Fe(CO) <sub>4</sub> ] | -0.45                          | 0                                  |

the axial symmetry leads to a low quadrupole splitting of  $\Delta E_Q = 0.42$  mm s<sup>-1</sup> (Table 1).

The Mössbauer spectrum of Fe<sub>3</sub>(CO)<sub>12</sub> shows two distinct iron sites, with a relative ratio of 2:1. In fact, this result led to the refinement of a crystal structure that had reported three equivalent iron sites. Although this happened in the early days of Mössbauer spectroscopy, that is, the 1960s, it

is an example of how Mössbauer spectroscopy can help refine crystal structure data. Later the correct structure of Fe<sub>3</sub>(CO)<sub>12</sub> had also been determined by X-ray diffraction and can be pictured as a Fe<sub>2</sub>(CO)<sub>9</sub> where a CO-bridge is replaced by a Fe(CO)<sub>4</sub> group.<sup>3</sup>

### 3.3 Iron(I) Compounds

Iron(I) compounds are quite rare. Münck *et al.* have recently reported a Mössbauer study of the mononuclear low-coordinate iron(I) compound LFe(HCCPh).<sup>33</sup> They show by a combined Mössbauer and electron paramagnetic resonance (EPR) study that the complex has a high-spin 3d<sup>7</sup> configuration ( $S = 3/2$ ) with near orbital degeneracy. The complex shows a sharp magnetic six-line pattern at 4.2 K and an external field of 50 mT. It exhibits an extraordinarily high hyperfine field of  $B_{\text{hf}} = +68.8$  T. The positive sign of  $B_{\text{hf}}$  has been determined from the observation that the magnetic splitting increases with increasing external fields. This behavior is completely different from the situation of most iron compounds and shows

that, in the case of  $\text{LFe}(\text{HCCPh})$ ,  $B_{\text{hf}}$  is clearly dominated by orbital contributions.

### 3.4 Iron(II) Compounds

#### 3.4.1 Low-Spin Iron(II)

Low-spin iron(II) ions are  $d^6$  with no unpaired electrons and are diamagnetic. The  $t_{2g}$  subshell is fully occupied, which leads to a symmetric charge distribution around the iron nucleus. Therefore, the electronic contribution to the electric field gradient should diminish and as a consequence low-spin iron(II) complexes are expected to have a very small or even undetectable quadrupole splitting. However, this is not always the case. Note that some low-spin ferrous heme proteins as well as heme model complexes have  $\Delta E_Q > 1 \text{ mm s}^{-1}$ . For example, for the heme model complex  $[\text{TMPFe}(\text{II})(1,2\text{-Me}_2\text{Im})_2]$ ,  $\Delta E_Q = 1.73 \text{ mm s}^{-1}$  has been reported.<sup>34</sup>

Because the shielding of the nucleus by the fully occupied  $t_{2g}$  subshell of low-spin iron(II) is less effective than in the case of high-spin iron(II) compounds (see Section 3.4.2), the charge density at the nucleus caused by the  $s$  electrons is increased compared to high-spin iron(II). This leads to isomer shifts ranging from  $-0.258 \text{ mm s}^{-1}$  at 298 K for sodium nitroprusside  $\text{Na}_2[\text{Fe}(\text{CN})_5\text{NO}] \cdot 2\text{H}_2\text{O}$  up to  $0.31 \text{ mm s}^{-1}$  for  $[\text{Fe}(\text{phen})_3](\text{ClO}_4)_2$  or even  $0.46 \text{ mm s}^{-1}$  for several ferrous low-spin heme models and cytochromes.<sup>34</sup>

The very low isomer shift of  $\text{Na}_2[\text{Fe}(\text{CN})_5\text{NO}] \cdot 2\text{H}_2\text{O}$ , a compound that has been often used as calibration standard, can be understood on the basis of the strong covalent effects present in the Fe–NO bond. The ground state of the iron in the nitroprusside molecules is  $(d_{xz}, d_{yz})^4(d_{xy})^2$ . The electrons in the orbitals with  $(d_{xz}, d_{yz})$  character are delocalized by back donation to the 2p orbitals of the NO ligand. In addition, as in the cyanides shown in Table 2,

there is also some slight delocalization from the  $d_{xy}$  orbital to the equatorial cyanides. Since there is also considerable 4s population, the electron density at the nucleus is much higher than usual, which manifests itself in the unusually low isomer shift.<sup>3</sup>

For the identification of low-spin iron(II), a low value of the quadrupole splitting is generally not enough. As an example, the Mössbauer spectrum of the reduced low-spin ferrous form of cytochrome  $c_{552}$  is shown in Figure 10. The reduced heme iron has  $\delta = 0.46 \text{ mm s}^{-1}$  and  $\Delta E_Q = +1.30 \text{ mm s}^{-1}$ .<sup>35</sup> These values are characteristic for the low-spin ferrous forms of several electron transfer heme proteins like cytochromes  $c$  and  $b$ .<sup>34</sup>

Measurements at 4.2 K and large external fields are the experimental choices to unambiguously identify diamagnetic iron species. A diamagnetic iron species exhibits a splitting of the Mössbauer spectrum in a high-field experiment, which is due only to the external field since the internal magnetic hyperfine field at the iron nucleus is zero. The Mössbauer spectrum of  $^{57}\text{Fe}$ -enriched cytochrome  $c_{552}$  obtained at 7 T is displayed in Figure 10(b). Note that the spectrum originates from a frozen protein solution. Therefore, the distribution of the molecules with respect to the direction of the external field is random (or powderlike) and hence the distribution of the electric field gradient tensor of the iron centers is also random. This fact has to be regarded if one wants to simulate high-field Mössbauer spectra of diamagnetic complexes. Such a situation can conveniently be handled in spin Hamiltonian simulations by setting all elements of the hyperfine coupling tensor  $\vec{A}$  to zero for an arbitrary spin  $S$ .

#### 3.4.2 High-Spin Iron(II) Compounds

High-spin iron(II) compounds with the iron in the  $S = 2$  state have rather high isomer shifts up to  $1.3 \text{ mm s}^{-1}$  at room temperature (Table 3), depending on the coordination

**Table 2** Mössbauer parameters of some six-coordinate low-spin Fe(II) ions. Note that the isomer shift decreases if the Fe–ligand bonds become more covalent in character. Mössbauer parameters for the cyanide complexes, as well as those for the phenanthroline complex, were taken from Greenwood and Gibb,<sup>3</sup> which the reader may consult for further references

**Figure 10** Mössbauer spectra of ferrous cytochrome  $c_{552}$  (a) Mössbauer spectrum of reduced cytochrome  $c_{552}$  obtained at  $T = 77$  K. The solid line represents a Lorentzian fit with  $\delta = 0.46 \text{ mm s}^{-1}$ ,  $\Delta E_Q = 1.30 \text{ mm s}^{-1}$ , and  $\Gamma = 0.27 \text{ mm s}^{-1}$ . (b) Field-dependent Mössbauer spectrum of reduced cytochrome  $c_{552}$  obtained at  $T = 4.2$  K in a field of 7 T perpendicular to the  $\gamma$  beam. The shape of the spectrum is characteristic of a diamagnetic powder or frozen solution sample with a positive sign of  $\Delta E_Q$ . For a negative  $\Delta E_Q$ , a reversed pattern would be observed. The solid line corresponds to a simulation with  $S = 0$ ,  $\delta = 0.46 \text{ mm s}^{-1}$ ,  $\Delta E_Q = 1.30 \text{ mm s}^{-1}$ ,  $\eta = 0.3$ , and  $\Gamma = 0.24 \text{ mm s}^{-1}$ . (From Zoppellaro, Teschner, Harbitz, Schünemann, Karlsen, Arciero, Ciurli, Trautwein, Hooper and Andersson.<sup>35</sup> Reprinted by permission of Wiley-VCH)<sup>35</sup>

number and the type of ligand. The high isomer shift is caused by the shielding of the outer s-electron charge density (mostly of 2s type) by the inner 3d electron charge density. In addition, the spin-down electron in the doubly occupied 3d orbital contributes significantly to the EFG. This leads to the fact that most high-spin iron(II) compounds have quadrupole splittings of around  $2\text{--}3 \text{ mm s}^{-1}$ .

The identification of high-spin iron(II) is one of the most straightforward problems to solve with Mössbauer spectroscopy. As an example, we will discuss the native

form of human tyrosine hydroxylase (hTH), which catalyzes the rate-limiting reaction in the biosynthesis of dopamine, noradrenaline, and adrenaline. The enzyme contains a nonheme iron center that is required for enzymatic function. All isoforms of hTH exhibit a quadrupole doublet with isomer shift  $\delta(1.6\text{--}77 \text{ K}) = 1.26\text{--}1.24 \text{ mm s}^{-1}$  and temperature-independent quadrupole splitting  $\Delta E_Q = 2.68 \text{ mm s}^{-1}$ .<sup>37</sup> These values are characteristic of high-spin Fe(II) in six-coordination with oxygen or nitrogen ligands. Shorter bond lengths in four-coordination with respect to six-coordination, as well as the presence of covalent ligands like sulfur as opposed to oxygen or nitrogen, would increase the s density at the Fe nucleus. This in turn would reduce the isomer shift. For four-coordination with ionic ligands, one would expect isomer shifts  $\leq 1 \text{ mm s}^{-1}$  below 77 K while alternatively six-coordination yields isomer shifts  $> 1.2 \text{ mm s}^{-1}$ . The empirical rule that reduction of the coordination number by one leads to a decrease of the isomer shift by an amount of  $\sim 0.1 \text{ mm s}^{-1}$  as discussed in Section 3.2 for covalent iron(0) compounds also holds here. In the same way, a substitution of one oxygen or nitrogen by one sulfur ligand would reduce the isomer shift by about  $0.1 \text{ mm s}^{-1}$ .

An X-ray crystallography study, on the related enzyme from rat reported a five-coordinate iron center. Since nuclear magnetic resonance (NMR) studies indicated the presence of a water molecule loosely bound to the iron, a Mössbauer study of dehydrated hTH was undertaken. Indeed, it has been found that 63% of the spectral area can be attributed to five-coordinate high-spin Fe(II) ( $\delta = 1.07 \text{ mm s}^{-1}$ ). After rehydration of hTH the spectroscopic changes were completely reversed.<sup>38</sup> The X-ray absorption spectra (see *X-Ray Absorption Spectroscopy*) of hTH corroborate the findings derived from the Mössbauer spectra. Thus, it was concluded that the active-site iron can exist in different coordination states, which can be interconverted depending on the hydration state of the protein, indicating the presence or absence of a water molecule as a coordinating ligand to the iron.

As a second example, Mössbauer spectra of a rubredoxin-type protein mutant from *Pyrococcus abyssi* are shown in Figure 11. This protein contains a tetrahedral sulfur-coordinated high-spin ferrous site. Owing to the covalent character of the Fe–S bond, an isomer shift of  $\sim 0.70 \text{ mm s}^{-1}$  is observed at 4.2 K. This value is characteristic for almost all tetrahedral sulfur-coordinated high-spin ferrous sites.

Although the high-spin ferrous site with  $S = 2$  is paramagnetic, no magnetic splitting is observed at 4.2 K. The reason is that the ground state spin expectation value of ions having integer spin in small magnetic fields goes to zero. The application of a moderate field of 1 T induces significant spin expectation values and therefore a magnetically split pattern is observed (Figure 11).<sup>39</sup>

The spin Hamiltonian analysis of the field-dependent Mössbauer spectra has been performed by a simultaneous fitting procedure of all spectra displayed in

**Table 3** Mössbauer parameters of some high-spin Fe(II) compounds (taken from Greenwood and Gibb<sup>3</sup>) in comparison to the ferrous high-spin site of human tyrosine hydroxylase. Note the decrease in isomer shift with decreasing coordination number

| Compound                                              | Iron coordination            | $\delta$ [mm s <sup>-1</sup> ] | $\Delta E_Q$ [mm s <sup>-1</sup> ] | $T$ [K] |

| (Me <sub>4</sub> N) <sub>2</sub> FeCl <sub>4</sub>    | 4Cl <sup>-</sup>             | 0.76                           | -0.72                              | 293     |
|                                                       |                              | 0.86                           | -2.61                              | 77      |
|                                                       |                              | 0.90                           | -3.27                              | 4.2     |
| (Me <sub>4</sub> N) <sub>2</sub> Fe(NCS) <sub>4</sub> | 4N                           | 0.82                           | 2.83                               | 4.2     |

Figure 11. The best fit has been found for  $\delta = 0.7 \pm 0.01$  mm s<sup>-1</sup>,  $\Delta E_Q = -3.25 \pm 0.01$  mm s<sup>-1</sup>,  $\vec{g} = (2.11, 2.19, 2.00)$ ,  $\vec{A}/g_N\mu_N = (-45, 10, 19)$  T,  $\eta = 0.74 \pm 0.1$ ,  $D = 7.2 \pm 0.5$  cm<sup>-1</sup>, and  $E/D = 0.16 \pm 0.02$ . The zero-field splitting parameter  $D = 7.2 \pm 0.5$  cm<sup>-1</sup> is comparable to that found for rubredoxin from *Clostridium pasteurianum* ( $D = 7.6$  cm<sup>-1</sup>).<sup>40</sup> Surprisingly, the rhombicity parameter  $E/D = 0.16 \pm 0.02$  differs somewhat from that of rubredoxin from *C. pasteurianum* ( $E/D = 0.28$ ). The hyperfine coupling tensor has been determined to be  $\vec{A} = (-14.5, -9.2, -27.5)$  T. The anisotropy of the hyperfine coupling tensor is caused by spin-orbit contributions to the internal magnetic hyperfine field.

It should be noted here that a correct determination of fine and hyperfine structure parameters should be done in such a way that spectra taken under different experimental conditions (variable external fields and/or variable temperatures) are reproduced with the same parameter set. This reproduction of the experimental data is often a bit less accurate than when one fits only a single experimental spectrum. However, owing to the many parameters involved in the simulation it makes absolutely no sense to deduce a complete spin Hamiltonian parameter set of a paramagnetic iron center from just one Mössbauer spectrum.

### 3.5 Iron(III) Compounds

#### 3.5.1 Low-Spin Iron(III) Compounds

Low-spin iron(III) ions have an electron hole in the  $t_{2g}$  orbitals. Therefore, these centers have  $S = 1/2$  and spin-orbit interaction contributes considerably to the magnetic hyperfine field. Low-spin iron(III) compounds in solution always show a rather complicated magnetic Mössbauer pattern at temperatures around 4.2 K and low external fields, which means that the relaxation rate of these centers is lower than the nuclear precession rate of  $\sim 10^{-7}$  s. Sometimes a magnetic splitting is observed even at 77 K. Therefore, in order to pin down  $\delta$  and  $\Delta E_Q$ , it is advisory to measure between 100 and

200 K, where the electronic relaxation rate becomes fast with respect to the Mössbauer time window and the limit of fast relaxation applies. Spin-spin interaction in microcrystals can also enhance the electronic relaxation rate and therefore some low-spin iron(III) compounds show quadrupole doublets even at 4.2 K.<sup>41</sup>

Since the iron 4s orbitals are involved in covalent bonding with the ligands, the s-electron density at the iron nucleus is increased compared to high-spin iron(II) compounds. This is even more true if  $\pi$ -accepting ligands like CN<sup>-</sup> are present. Therefore the difference in isomer shift between low-spin iron(II) and low-spin iron(III) is much less pronounced than between high-spin iron(II) and high-spin iron(III).

As an example of how to determine the electronic ground state of a low-spin iron(III) compound, we present work on the ferric low-spin heme complex [TPPFe(NH<sub>2</sub>PzH)<sub>2</sub>]Cl, which has been shown to have a  $(d_{xy})^2(d_{xz}, d_{yz})^3$  electronic ground state.<sup>42</sup> The field-dependent Mössbauer spectra of [TPP<sup>57</sup>Fe(NH<sub>2</sub>PzH)<sub>2</sub>]Cl displayed in Figure 12 are well reproduced by simulations, which yield  $\delta = 0.25$  mm s<sup>-1</sup>,  $\Delta E_Q = (+)2.50$  mm s<sup>-1</sup>, an asymmetry parameter  $\eta = -3$ , and an anisotropic A tensor of  $\vec{A}/g_N\mu_N = (-47.6, 6.7, 18.3)$  T. The  $g$  values necessary for the  $S = 1/2$  spin Hamiltonian ( $g_{zz} = 2.39$ ,  $g_{yy} = 2.28$ , and  $g_{xx} = 1.87$ ) have been taken from a combined EPR and electron spin echo envelope modulation spectroscopy ESEEM analysis.

The calculation of the corresponding A tensor according to the model of Oosterhuis and Lang<sup>43</sup> in the reference frame chosen by Taylor<sup>44</sup> yields  $\vec{A}/g_N\mu_N = (-47.6, 11.7, 18.3)$  T, which is in very good agreement with the experimental values. The fact that the electronic ground state predominantly exhibits  $d_{yz}$  character also allows determination of the anisotropy parameter  $\eta$ , if one neglects the ligand contribution to the EFG.<sup>24</sup> A value of  $\eta \cong -3$  has been obtained, which is in excellent agreement with the experiment. The EFG is nearly axially symmetric around the  $x$  axis of the molecular frame. The coordinate system of the EFG tensor ( $x'$ ,  $y'$ ,  $z'$ ) is commonly chosen in such a way

**Figure 11** Mössbauer spectrum of the rubredoxin-type protein mutant RM-2-4 from the archaeon *P. abyssi* taken at 4.2 K and fields indicated. The structure of the iron site is shown at top right. The solid lines have been obtained by simultaneous fitting of the Mössbauer spectra with the software package VINDA for an  $S = 2$  ground state. The parameters obtained are described in the text. (From Wegner *et al.*<sup>39</sup> With kind permission from Springer Science & Business Media)

that  $|V_{z'z'}| \geq |V_{y'y'}| \geq |V_{x'x'}|$ , which means that the coordinate system of the EFG tensor is turned around the  $y$  axis of the molecular frame by the Euler angle  $\beta = 90^\circ$ . In this coordinate system,  $\eta' \approx 0$  and  $\Delta E'_Q = (-)2.50 \text{ mm s}^{-1}$ . A hole in the  $t_{2g}$  orbitals contributes to the quadrupole splitting by an amount of  $\sim 3 \text{ mm s}^{-1}$ .<sup>24</sup> The experimental value of  $\Delta E_Q = 2.50 \text{ mm s}^{-1}$  for  $[\text{TPP}^{57}\text{Fe}(\text{NH}_2\text{PzH})_2]\text{Cl}$  confirms this empirical observation.

Thus, Mössbauer spectroscopy corroborates the results of the ESEEM studies, which give  $\vec{g} = (2.39, 2.28, 1.87)$  and clearly show an electronic ground state

with major  $d_{yz}$  character. The hyperfine coupling constants of the bis-3-aminopyrazole complex are, in fact, very similar to those of the low-spin form of cytochrome P450<sub>cam</sub>, for which Debrunner *et al.* reported  $\vec{A}/g_N\mu_N = (-45, 10.2, 19.1) \text{ T}$ .<sup>45</sup> In spite of the similarity in  $A$  values, the  $g$  values of the P450<sub>cam</sub> species are 2.45, 2.26, and 1.91, somewhat different from those of the 3-aminopyrazole complex discussed here. The largest component of the electric field gradient tensor with respect to the molecular frame is the  $x$  component and is negative. The  $z$  component of the hyperfine coupling tensor is positive and only about half the magnitude of the

**Figure 12** Field-dependent Mössbauer spectra of the ferric low-spin heme complex  $[\text{TPPFe}(\text{NH}_2\text{PzH})_2]\text{Cl}$ . The solid lines are spin Hamiltonian simulations for  $S = 1/2$  with parameters discussed in the text and given in Ref. 42 (From Schünemann *et al.*<sup>42</sup> With kind permission from Springer Science & Business Media)

$x$  component. This is also consistent with a singly occupied  $d_{yz}$  orbital, although most other  $(d_{xy})^2(d_{xz}, d_{yz})^3$  electronic ground state systems except for cytochrome P450<sub>cam</sub> have  $A_{zz}$  as the largest component.

### 3.5.2 High-Spin Iron(III) Compounds

The iron centers of high-spin iron(III) compounds have a half-filled 3d electron shell with each 3d orbital singly occupied. This electron configuration leads to a symmetric charge distribution around the iron nucleus. Therefore, highly symmetric high-spin iron(III) compounds in general exhibit low values of the quadrupole splitting. This holds specially for highly symmetric octahedral halogen iron compounds like  $\text{FeF}_3$  and  $\text{FeCl}_3$  which have almost zero quadrupole splittings. The isomer shifts of octahedrally coordinated high-spin iron(III) complexes are in general around  $0.5 \text{ mm s}^{-1}$  at cryogenic temperatures except if sulfur ligands are present, which tends to decrease the isomer shift.

Octahedral iron(III) complexes with nitrogen and/or oxygen as ligand have isomer shifts ranging from 0.4 to  $0.6 \text{ mm s}^{-1}$ . Tetrahedral coordination enhances the electron density at the nucleus and therefore leads to slightly reduced isomer shifts but this effect is not as pronounced as in high-spin iron(II) complexes. Therefore, it is not straightforward to distinguish between different coordination numbers of ferric high-spin iron. An exception is tetrahedral ferric high-spin centers in iron–sulfur proteins. They exhibit an isomer shift

of  $0.24 \text{ mm s}^{-1}$  at 4.2 K, and it has been shown that a 2N2S coordination leads to a slight increase in isomer shift by about  $0.08 \text{ mm s}^{-1}$ . For example, the Mössbauer spectrum of the oxidized Rieske cluster from *Thermus thermophilus*<sup>46</sup> consists of two doublets, which reflects the difference in ligand geometry of the two tetrahedral high-spin iron(III) sites. One doublet has  $\delta_1 = 0.24 \text{ mm s}^{-1}$  and  $\Delta E_{Q1} = 0.52 \text{ mm s}^{-1}$  and the other has  $\delta_2 = 0.32 \text{ mm s}^{-1}$  and  $\Delta E_{Q2} = 0.91 \text{ mm s}^{-1}$  at 4.2 K. The former values are practically identical with those found for oxidized rubredoxin, which has a tetrahedral sulfur-coordinated ferric high-spin iron site. The latter values are still comparable with  $S = 5/2$  ferric irons and represent a tetrahedral iron(III) site with 2N2S coordination. This was proposed on the basis of the Mössbauer data and was confirmed by X-ray crystallography almost a decade after the initial Mössbauer study by Münck *et al.*<sup>46</sup>

In the following text, we discuss the extraction of  $D$  from field-dependent Mössbauer spectra recorded at  $T = 4.2 \text{ K}$  by means of the spin Hamiltonian formalism for a single iron center in the  $\text{Fe(III)} S = 5/2$  state. The variation of parameters was carried out by simultaneous simulation of the spectra shown in Figure 13 and of spectra recorded at 4.2 K in a field of 20 mT (data not shown). It should be noted that the rhombicity parameter  $E/D$  has been determined from a complementary EPR measurement, which is advisory if spin Hamiltonian simulations of  $S = 5/2$  systems are performed to decrease the number of parameters. The EPR spectrum of oxidized RM-2–4 exhibits a broad distribution of effective  $g$  values around 4.3 consistent with  $E/D = 0.28$ . Therefore, this value was taken as initial input parameter for the simulations of the Mössbauer spectra. The best fit has been found for  $\delta = 0.24 \pm 0.01 \text{ mm s}^{-1}$ ,  $\Delta E_Q = -0.36 \pm 0.01 \text{ mm s}^{-1}$ ,  $\vec{g} = (2.0, 2.0, 2.0)$  (fixed),  $\vec{A}/g_N\mu_N = (-17.7, -15.7, -16.4) \text{ T}$ ,  $\eta = 0.80 \pm 0.2$ ,  $D = 2.13 \pm 0.6 \text{ cm}^{-1}$ , and  $E/D = 0.23 \pm 0.03$ . The hyperfine coupling tensor  $\vec{A}$  is almost isotropic, which means that the isotropic Fermi-contact interaction is dominant and spin-orbit interaction contributes only marginally to the anisotropy of  $\vec{A}$ . The mean value of the hyperfine coupling tensor  $A/\mu_N g_N = -16.6 \text{ T}$  (corresponding to  $B_{\text{hf}} = -41.5 \text{ T}$ ) is characteristic for iron in tetrahedral sulfur coordination. This value is considerably smaller than  $A/\mu_N g_N = -22 \text{ T}$  (corresponding to  $B_{\text{hf}} = -55 \text{ T}$ ) typically found for ferric high-spin ions with oxygen and/or nitrogen coordination.

### 3.6 Iron(IV) Compounds

Four-valent iron centers are well known as catalytic intermediates in enzymatic heme catalysis. The catalytic cycles of, for example, catalase, peroxidase, and cytochrome P450, all have in common an intermediate that is comprised of a ferryl  $\text{Fe(IV)}$  and a further oxidation equivalent located either on the heme ring or on the protein moiety. This reaction intermediate is called compound I (cpd I) and has a system spin of  $S = 1/2$  (e.g., in chloroperoxidase) or  $S = 3/2$  (e.g.,

**Figure 13** Mössbauer spectra of the oxidized rubredoxin-type protein mutant RM-2-4 from the archaeon *Pyrococcus abyssi* taken at 4.2 K in applied field perpendicular (a) and parallel (b) to  $\gamma$ -ray. The solid lines have been obtained by simultaneous fitting of the Mössbauer spectra with the software package VINDA assuming an  $S = 5/2$  ground state.<sup>27</sup> The parameters are described in text. (From Wegner *et al.*<sup>39</sup> With kind permission from Springer Science & Business Media)

in catalase and many heme model compounds). Mössbauer spectroscopy continues to contribute to the understanding of the formal oxidation state of these intermediates. The reduction of cpd I by one electron equivalent leads to a ferryl Fe(IV) heme complex with almost the same isomer shift as cpd I. Heme iron(IV) compounds are characterized by their low isomer shifts around  $0 \text{ mm s}^{-1}$ . Ferryl heme iron has a  $d^4$  configuration with the lowest lying  $d_{xy}$  orbital being doubly occupied and the  $d_{yz}$  and  $d_{xz}$  orbitals being singly occupied. This leads to a total spin of  $S = 1$ . As an overview, the isomer shifts and quadrupole splittings of some Fe(IV) hemes are displayed in Table 4.

The situation in the case of nonheme Fe(IV) intermediates is somewhat different. It has been recently shown by Krebs and coworkers that a catalytically competent Fe(IV) intermediate in the  $\alpha$ -ketoglutarate-dependent dioxygenase TauD has a high-spin  $S = 2$  configuration.<sup>48</sup> TauD is a member of a large family of enzymes that catalyze reactions in the biosynthesis of antibiotics, collagen, degradation of xenobiotics, and biosynthesis of antioxidants. Mössbauer spectroscopy of rapid-freeze-quenched (RFQ) samples identified an intermediate named J upon the reaction of a TauD–Fe(II):  $\alpha$ -ketoglutarate–taurine complex in the time regime from 20 to 200 ms. The time dependence of the concentration of J correlates with a UV-absorption band at 320 nm. The intermediate J showed a quadrupole doublet with  $\delta = 0.31 \text{ mm s}^{-1}$  and  $\Delta E_Q = 0.88 \text{ mm s}^{-1}$  even at  $T = 4.2 \text{ K}$  in a weak field of 40 mT (Figure 14).<sup>49</sup>

The application of external fields up to 8 T induced a magnetic splitting, which has been analyzed assuming an  $S = 2$  ground state. This example is a very nice piece of work illustrating how the spin and oxidation state can be deduced from Mössbauer spectroscopy. Therefore, we will explain these assignments in more detail by raising some questions:

**Figure 14** Mössbauer spectra of intermediate J of  $\alpha$ -ketoglutarate-dependent dioxygenase TauD obtained at 4.2 K and fields indicated. The solid line represents a simulation using an  $S = 2$  spin Hamiltonian and the parameters  $\delta = 0.31 \text{ mm s}^{-1}$ ,  $\Delta E_Q = -0.88 \text{ mm s}^{-1}$ ,  $\eta = 0.0$ ,  $\vec{A}/g_N\mu_N = (-18, -18, -18) \text{ T}$ ,  $g = (2.3, 2.3, 2)$ ,  $E/D = 0.03$ , and  $D = 10.5 \text{ cm}^{-1}$ . (Reprinted with permission from Krebs, Price, Baldwin, Saleh, Green and Bollinger.<sup>48</sup> © 2005 American Chemical Society)

Question 1: Both  $\delta$  and  $\Delta E_Q$  are within the range of Fe(III) species with an  $S = 5/2$  ground state. Could J have this kind of ground state?

Answer: No! The Mössbauer spectrum of J does not show magnetic splitting at  $T = 4.2 \text{ K}$  and weak external field, which would be expected for an isolated ferric high-spin iron.

Question 2: Why does J have an integer spin?

Answer: Spin expectation values (and therefore the magnetic hyperfine field) of half-integer spin systems can be saturated in low fields (see Section 3.5.2). This is not the case here. In order to drive the magnetic splitting to its saturation, fields of up to 8 T have been applied. In addition, J is EPR silent, which points to an integer-spin species.

Question 3: Can J be an exchange-coupled Fe(III) dimer? These are EPR silent and also show only a doublet at 4.2 K and weak field.

Answer: Although this may be ruled out from the biochemistry perspective, it is worth considering this question from the Mössbauer spectroscopic point of view: Strongly exchange-coupled ferric iron dimers like those in methane monooxygenase, ribonucleotide reductase, and  $\text{Fe}_2\text{S}_2$  iron-sulfur proteins all have a diamagnetic ground state. The magnetic splitting of

J clearly exceeds that of the applied external fields. Therefore J cannot be diamagnetic.

Question 4: Ultrasmall superparamagnetic particles can relax faster than the time window of Mössbauer spectroscopy even at 4.2 K and such ferric nanoparticles also show similar  $\delta$  and  $\Delta E_Q$  values.

Answer: The relaxation rate of superparamagnetic particles would be slowed down by the application of large external fields. What one normally observes is a magnetically split spectrum with broad lines and almost negligible quadrupole splitting (see e.g., Figure 7). The reason is that the main axis of the electric field gradient tensor of the surface atoms of such clusters is oriented in all directions with respect to the direction of the magnetic hyperfine field. This is often observed in reconstitution experiments of iron-sulfur proteins. If the reader is interested, Figure 4 of the work on anaerobic ribonucleotide reductase by Ollagnier *et al.*,<sup>50</sup> which serves as an example of small superparamagnetic iron-sulfur agglomerates, may be referred to.

Question: How can a spin state of  $S = 1$  be ruled out from the spectra?

Answer: The authors did indeed evaluate the Mössbauer data by spin Hamiltonian simulations assuming an  $S = 2$  as well as an  $S = 1$  ground state. In this way they could deduce two sets of hyperfine and fine structure parameters: simulations assuming an  $S = 1$  ground state yield an axial hyperfine tensor  $\vec{A}_{x,y}/g_N\mu_N = -33.3 \text{ T}$ . Such a high hyperfine coupling tensor has never been observed for ferryl iron species having  $S = 1$ . The isotropic hyperfine coupling tensor  $\vec{A}/g_N\mu_N = -18 \text{ T}$  which has been obtained assuming an  $S = 2$  ground state is in the range of hyperfine coupling tensors observed for ferryl iron species.

The groups of Que and Münck have reported the synthesis of the nonheme Fe(IV)=O model compound  $[(\text{Fe(IV)=O})(\text{TMC})(\text{NCCH}_3)](\text{OTf})_2$ , which contains a nonheme macrocyclic ligand.<sup>51</sup> In zero applied field, the complex exhibits a Mössbauer spectrum consisting of a doublet with  $\delta = 0.17 \text{ mm s}^{-1}$  and  $\Delta E_Q = 1.24 \text{ mm s}^{-1}$ . The spin Hamiltonian analysis of the Mössbauer spectra in high fields between 4.2 and 100 K shows that  $[(\text{Fe(IV)=O})(\text{TMC})(\text{NCCH}_3)](\text{OTf})_2$  has integer electronic spin. Spectral simulations using an  $S = 1$  spin Hamiltonian yield  $\delta = 0.17(1) \text{ mm s}^{-1}$ ,  $\Delta E_Q = +1.24 \text{ mm s}^{-1}$ ,  $\eta = 0.5$ ,  $\vec{A}/g_N\mu_N = (-25, -20, -3) \text{ T}$ ,  $g = (2.3, 2.3, 2)$ ,  $E/D = 0$ , and  $D = 29 \text{ cm}^{-1}$ . In their analysis, the  $z$  component of the  $g$  tensor was set to 2.0 and the  $x$  and  $y$  components were calculated according to  $g_{x,y} = 2.0 + 4D/\zeta$ , with  $\zeta$  being the single-electron spin-orbit coupling constant. This parameter set compares well with those of Fe(IV)=O complexes having  $S = 1$ , which show  $A_{x,y} \sim 17 - 25 \text{ T}$  and a relatively large zero-field splitting  $D \sim 20 - 37 \text{ cm}^{-1}$ .

It is instructive to compare the Mössbauer properties of  $[(\text{Fe(IV)=O})(\text{TMC})(\text{NCCH}_3)](\text{OTf})_2$  with those of the

**Figure 15** (a) The 4.2 K Mössbauer spectra of  $[(\text{Fe(IV)=O)(TMC)(NCCH}_3)](\text{OTf})_2$  in acetonitrile recorded in (A) zero field and (B) a parallel field of 6.5 T. The solid line represents a spin Hamilton simulation with the parameters described in the text. (b) Mössbauer spectra of  $[\text{Fe(IV)=O)(TMCS)}]$  recorded at temperatures and applied fields that are indicated. The solid lines represent spin Hamiltonian simulations with parameters described in the text. The spectra were simulated in the slow (at 4.2 K) and fast (at 30 K) spin fluctuation limit. The applied field was directed parallel to the observed  $\gamma$  radiation. The doublet drawn above the topmost experimental spectrum (0 T, 4 K) represents a 7% Fe(II) contribution from the starting complex. (From J. U. Rohde *et al.* (2003) *Science* **299**:1037–1039. Reprinted with permission from AAAS)

complex  $[\text{Fe(IV)=O)(TMCS)}]$ .<sup>52</sup> TMCS, the monoanion of 1-mercaptoethyl-4,8,11-trimethyl-1,4,8,11-tetraaza cyclotetradecane, is a pentadentate ligand that provides a square pyramidal N4(SR) ligand environment about the iron center, which is similar to that of cytochrome P450, containing an axial  $\text{RS}^-$  ligand. At zero field,  $[\text{Fe(IV)=O)(TMCS)}]$  exhibits a doublet with  $\delta = 0.19 \text{ mm s}^{-1}$  and  $\Delta E_Q = 0.22 \text{ mm s}^{-1}$ . A spin Hamiltonian analysis of the high-field Mössbauer spectra (Figure 15) assuming  $S = 1$  yields a negative sign for the quadrupole splitting and an asymmetry parameter  $\eta = 0$ . The hyperfine coupling tensor has been determined as  $\vec{A}/g_N\mu_N = (-23, -22, -5) \text{ T}$  and the fine structure parameters as  $E/D = 0$  and  $D = 35 \text{ cm}^{-1}$ . Surprisingly, the isomer shift of  $[\text{Fe(IV)=O)(TMCS)}]$  is comparable with that of  $[(\text{Fe(IV)=O)(TMC)(NCCH}_3)](\text{OTf})_2$  within the experimental error of  $\pm 0.01 \text{ mm s}^{-1}$ . However the quadrupole splitting is significantly smaller and even reverses its sign in the thiolate complex ( $\Delta E_Q = -0.22 \text{ mm s}^{-1}$  for  $[\text{Fe(IV)=O)(TMCS)}]$  versus  $\Delta E_Q = +1.25 \text{ mm s}^{-1}$  in  $[(\text{Fe(IV)=O)(TMC)(NCCH}_3)](\text{OTf})_2$ ).

### 3.7 Iron(V) Compounds

Iron(V) complexes are very rare, but recently two examples involving the characterization of these compounds with Mössbauer spectroscopy have been reported in the literature. Meyer *et al.* reported on the spectroscopic

characterization of a nitridoiron(V) species prepared by photolysis of  $[\text{Fe(III)(cyclam)(N}_3)_2]^+$  complexes.<sup>53</sup> Mössbauer spectroscopy of this species yields  $\delta = -0.04 \text{ mm s}^{-1}$  and  $\Delta E_Q = -1.90 \text{ mm s}^{-1}$  at 80 K and it has a spin state  $S = 3/2$  (determined by EPR). The spin Hamiltonian parameters obtained by Mössbauer spectroscopy are consistent with this picture. The analysis yields  $D = -0.37 \text{ cm}^{-1}$ ,  $E/D = 0.095$ ,  $g = 2.0$  (isotropic),  $\vec{A}/g_N\mu_N = (-13.3, -10.6, 2.5) \text{ T}$  and  $\eta = 0.6$ .

Very recently, chemical and spectroscopic evidence for an Fe(V)-oxo-complex has been reported by de Oliveira *et al.*<sup>54</sup> Field- and temperature-dependent Mössbauer as well as X-ray absorption (*see X-Ray Absorption Spectroscopy*) and EPR spectroscopies in combination with density functional theory DFT calculations show that  $[\text{Fe(TAML)(O)}]^-$  with TAML being a macrocyclic tetraamide ligand is a  $d^3$  system with spin  $S = 1/2$  and  $\delta = -0.42 \text{ mm s}^{-1}$ ,  $\Delta E_Q = +14.25 \text{ mm s}^{-1}$ ,  $\eta = 0.65$ ,  $A/\mu_N g_N = (-49.3, -1.5, -16.3) \text{ T}$  and  $g = (1.99, 1.97, 1.74)$ . The hyperfine parameters have also been determined by DFT using Gaussian with the functional B3LYP and the basis set G-311G with admirable accuracy ( $\delta = -0.39 \text{ mm s}^{-1}$ ,  $\Delta E_Q = +4.51 \text{ mm s}^{-1}$ ,  $\eta = 0.72$ ,  $\vec{A}/\mu_N g_N = (-43.6, -0.5, -15.0) \text{ T}$ ).

### 3.8 Iron(VI) Compounds

Until very recently, only a single Fe(VI) species, the ferrate ion  $[\text{Fe(VI)O}_4]^{2-}$ , was known. This species is a

strong oxidant and used not only in organic synthesis but also in waste water treatment, batteries, and disinfectants. The Fe(VI) compound  $\text{K}_2\text{FeO}_4$  has a single-line resonance at  $-0.78 \text{ mm s}^{-1}$  at 78 K.

Very recently, a photochemical synthesis of an Fe(VI) compound has been reported by the Wieghardt group.<sup>55</sup> The octahedrally coordinated iron in  $[(\text{Me}_3\text{cy-ac})\text{FeN}](\text{PF}_6)_2$  has a  $\text{Fe}\equiv\text{N}$  triple bond of  $1.57 \text{ \AA}$  as shown by X-ray absorption spectroscopy. Mössbauer spectroscopy in a field of 7 T shows that the iron is diamagnetic and that the sign of  $\Delta E_Q$  is positive (Figure 16).

DFT calculations reproduce the positive sign of  $\Delta E_Q$  and indicate that  $[(\text{Me}_3\text{cy-ac})\text{FeN}](\text{PF}_6)_2$  has a doubly occupied nonbonding  $d_{xy}$  orbital and a strong covalent iron–nitrogen bond. Surprisingly the isomer shift of this complex ( $\delta = -0.29 \text{ mm s}^{-1}$ ) is much higher than that of  $[\text{Fe(VI)O}_4]^{2-}$ , which has  $\delta$  values between  $-0.79$  and  $-0.85 \text{ mm s}^{-1}$ , depending on the type of salt.

In such a situation, the only clear cut strategy that leads to a definite answer concerning the valence state of the iron is not only to apply spectroscopic methods complementary to Mössbauer spectroscopy but also to investigate complexes with similar ligands but different electronic configurations. In order to clarify the electronic configuration of  $[(\text{Me}_3\text{cy-ac})\text{FeN}](\text{PF}_6)_2$ , X-ray absorption spectroscopy (XAS) has

**Figure 16** Mössbauer spectra of a acetonitrile solution of  $[(\text{Me}_3\text{cy-ac})\text{Fe(VI)N}](\text{PF}_6)_2$  measured at 80 K (A) and at 4.2 K in a magnetic field of 7 T (B). The magnetic splitting in B corresponds to the external field. The simulation has been performed by assuming a diamagnetic species. Subspectrum (a) corresponds to a stable  $[(\text{Me}_3\text{cy-ac})\text{Fe(IV)N}_3](\text{PF}_6)_2$  and was the only subspectrum that was fitted in (B). (From J. F. Berry *et al.* (2006) *Science* **312**:1937–1941. Reprinted with permission from AAAS)

been chosen as a method complementary to Mössbauer spectroscopy and the spectroscopic signatures of a series of iron complexes with valence states ranging from Fe(II) to Fe(VI) have been studied. Figure 17 displays a plot of the isomer shifts versus iron oxidation states for a series of low-spin iron complexes with cyclam-related ligands having oxidation states from II to VI. Not only the isomer shift scales beautifully with the oxidation number, but also the XAS pre-edge-energy, which is also an indicator for iron oxidation states, exhibits a linear correlation with the iron oxidation states of the complexes.

Together with the reproduction of  $\delta$  and  $\Delta E_Q$  values by DFT calculations, this piece of work is a beautiful example of how Mössbauer spectroscopy can be used to determine spin and oxidation states of high-valent iron. The authors do claim that in fact Fe(VI) intermediates that are undetected until now might exist in chemical and/or enzymatic reactions.

### 3.9 Molecules with Iron Centers of Higher Nuclearity

There are many iron proteins and corresponding model complexes that have more than one iron site. Dinuclear iron centers are present in 2Fe–2S electron transfer proteins or in enzymes like methane monooxygenase and ribonucleotide reductases. Even high-valent reaction intermediates have been detected by the RFQ Mössbauer studies of Huynh *et al.*<sup>56</sup> A broad variety of 3Fe–4S and 4Fe–4S proteins exist and enzymes like hydrogenases and nitrogenases have even more complex iron centers. Mössbauer spectroscopy detects all  $^{57}\text{Fe}$  in the sample, which is a big advantage if compared, for example, with EPR, and therefore all the systems mentioned above have been and are still investigated using this technique.<sup>7,8,11</sup>

**Figure 17** Plot of the isomer shifts versus Fe oxidation state of a series of low-spin Fe(III) Fe(IV), Fe(V), and Fe(VI) complexes with cyclam-related ligands. A plot of the Fe X-ray absorption spectroscopy (XAS) pre-edge peak energies of some complexes versus Fe oxidation state is also shown (open squares). The lines with dashes and dots represent least squares fits. (From J. F. Berry *et al.* (2006) *Science* **312**:1937–1941. Reprinted with permission from AAAS)

Mössbauer spectra of exchange-coupled iron centers having a paramagnetic ground state are almost exclusively evaluated in the strong-exchange limit. This implies that all exchange interactions are assumed to be strong and that no excited states are populated under the conditions at which the Mössbauer spectra are recorded. Only in this case is it justified to assume that the center can be described by a system spin  $S$ . Therefore, it is possible to evaluate the Mössbauer spectra in terms of the conventional spin Hamiltonian (equation 18). This procedure yields the system spin  $S$  as well as the parameters  $D$ ,  $E/D$ ,  $g$ , and  $A$ . The parameters of the single iron sites can be obtained by the spin-projection technique, which is also used in evaluating EPR spectra of strongly exchange-coupled systems. Instructive examples of this procedure can be found in Ref. 57.

Here we limit ourselves to an example of a 4Fe–4S center from the radical *S*-adenosyl-L-methionine (SAM) enzyme oxygen-independent coproporphyrinogen III oxidase HemN.<sup>58</sup> This enzyme catalyzes the oxidative decarboxylation of coproporphyrinogen III to protoporphyrinogen IX during bacterial heme biosynthesis. The crystal structure of *Escherichia coli* HemN revealed the presence of an unusually coordinated iron–sulfur cluster and two molecules of SAM.

The Mössbauer spectra of HemN without further additions are shown in Figure 18(a) and the parameters obtained are summarized in Table 5. The corresponding three iron atoms are ligated by cysteines ( $\delta_1 = 0.43(1) \text{ mm s}^{-1}$ ,  $\Delta E_{Q1} = 1.17(1) \text{ mm s}^{-1}$ ) whereas the fourth is not ( $\delta_2 = 0.57(3) \text{ mm s}^{-1}$ ,  $\Delta E_{Q2} = 1.23(2) \text{ mm s}^{-1}$ ). A

value of  $\delta \sim 0.45 \text{ mm s}^{-1}$  is typical for valence-delocalized  $\text{Fe}^{2.5+}\text{--Fe}^{2.5+}$  pairs with one electron being delocalized over the two iron sites. The value  $\delta_2 = 0.57(3) \text{ mm s}^{-1}$  is clearly outside this range. Therefore, the ligand of the fourth iron site is unknown in the absence of SAM. Possible candidates could be either an amino acid residue of the polypeptide other than cysteine or alternatively any molecule contained within the buffer solution. These results are consistent with the finding that only the three cysteine residues C62, C66, C69 within the CXXXCXXC motif of *E. coli* HemN are involved in iron–sulfur cluster coordination.

Figure 18(b) shows the Mössbauer spectra of HemN plus SAM. As in the case of HemN, two different iron sites of a  $[\text{4Fe--4S}]^{2+}$  cluster were identified for the HemN spectra in the presence of SAM. However, for the latter spectra, a change in the isomer shift of the non-cysteine-ligated iron atom (from  $\delta_2 = 0.57(3) \text{ mm s}^{-1}$  to  $\delta_2 = 0.68(3) \text{ mm s}^{-1}$ ) was observed, which indicates that SAM only binds at one iron of the cluster, namely this unique, non-cysteine-ligated iron atom. This is consistent with the observed coordination of SAM to the iron–sulfur cluster in the crystal structure of *E. coli* HemN, in which it was observed that SAM binds at the iron by means of the carboxy and the amino group of the methionine part of SAM. Thus SAM coordination to the fourth iron site of the cluster is analogous in solution and in the crystalline state of HemN. The isomer shift value for the SAM ligated iron site can be directly correlated with specified distances between the iron and the ligand atoms in the case of HemN. Thus, the observed isomer shift of  $\delta_2 = 0.68(3) \text{ mm s}^{-1}$  is

**Figure 18** Mössbauer spectra of HemN in the absence (a) and in the presence of SAM (b). Spectra were obtained at  $T = 4.2 \text{ K}$  in an external magnetic field of (A) 20 mT and (B) 4 T perpendicular to the  $\gamma$  beam. The parameters are given in Table 5. <sup>(a)</sup>The Fe<sup>2+</sup>–4S component was not resolved in the 4T measurement.

associated with the iron site, which is ligated by the O- (2.3 Å) and the N-ligand (2.6 Å) of the methionine part of SAM as observed in the crystal structure of HemN. Therefore, the Mössbauer results provide essential information in correlation with the structural data, namely the possibility to combine the structural features (distances between the atoms) with the electronic properties (Mössbauer parameters) of the [4Fe–4S] cluster of HemN.

### 3.10 Prediction of Mössbauer Parameters by Density Functional Calculations

Since the early days of application of Mössbauer spectroscopy in solid state physics and inorganic chemistry, electronic structure calculations have been performed to rationalize and predict the Mössbauer parameters obtained. In the beginning, calculations were applied to single ions, but later semiempirical methods could be applied to small molecules, too. Early density functional theory (DFT) methods, like the self-consistent charge (SCC)-X $\alpha$  method could be successfully applied to larger molecules. For more than a decade, DFT methods with all-electron basis sets have also been applied to large bioinorganic molecules. These methods allow the determination of Mössbauer parameters with impressive accuracy and have become a valuable tool for the interpretation of Mössbauer spectra.

#### 3.10.1 Density Functional Calculations

Density functional theory is based on the Hohenberg–Kohn theorems,<sup>59</sup> which state (i) that there is a one-to-one mapping between the electronic charge density

$\rho_0$  and the wavefunction  $\Psi_0$  of the ground state and (ii) that there is a functional  $E[\rho]$  that maps the density on the molecular energy and that is minimized by the ground state density  $\rho_0$ . In this way, the solution of the Schrödinger equation for an  $N$ -particle wavefunction is reduced to the problem of minimizing the energy functional  $E[\rho]$  by a one-particle charge density. The price for this reduction of complexity is that only approximations for the functional  $E[\rho]$  are available, the exact form being unknown. Actually, Before the formulation of the Hohenberg–Kohn theorems, Slater had already proposed the SCC-X $\alpha$  method,<sup>60,61</sup> which is now regarded as the first DFT method. For most of the problems that are addressed by electronic structure calculations, DFT methods became the method of choice. Although ab initio methods can, in principle, give results with any desired accuracy, they are at the current stage for most purposes computationally too demanding to compete with DFT methods in the field of transition metal compounds.

#### 3.10.2 Electric Field Gradient and Quadrupole Splitting

The quadrupole splitting  $\Delta E_Q$  is the first Mössbauer parameter that could be predicted with reasonable accuracy by electronic structure calculations. The quadrupole splitting can be related to the EFG at the Mössbauer nucleus according to equation (12). Since the nuclear quadrupole moment  $Q$  is very difficult to determine by experiment alone, the combination of Mössbauer spectroscopy and density functional calculations is currently the most accurate approach to estimate  $Q$ . A linear regression of measured quadrupole splittings and calculated electric field gradients has been performed by Blaha *et al.*<sup>62</sup> for a large series of compounds

**Figure 19** Calculated electric field gradients versus observed quadrupole splittings  $\Delta E_Q$ . The solid line represents a linear regression with a  $^{57}\text{Fe}$  nuclear quadrupole moment of 0.17 barns. (From Blaha, Schwarz, Faber and Luitz.<sup>62</sup> With kind permission from Springer Science & Business Media)

covering a wide range of different quadrupole splittings (Figure 19). According to these calculations, a value of the nuclear quadrupole moment of the  $^{57}\text{Fe}$  nucleus of 0.15–0.17 barn is commonly accepted, with an uncertainty of about 10%.

Successful calculations of the quadrupole splitting have been performed with a variety of density functional methods. Among the currently most popular functionals—like the gradient corrected functionals BP86 or BPW91 or the hybrid functional B3LYP—there are no apparent differences in the quality of the predicted field gradients. Zhang and Oldfield<sup>63</sup> demonstrated that wrong iron–ligand bond lengths are a major source of error for calculated field gradients. Methods employing the local density approximation, which are notorious for underestimating metal–ligand bond lengths, are in principle expected to give less accurate field gradients than corrected gradient functionals. However, this effect may be canceled by other sources of error working in the opposite direction.

Several studies<sup>63–65</sup> have shown that the calculated field gradients are sensitive to the quality of the size of the basis set. The type of basis set, for example, Gaussian-type orbitals (GTOs) or Slater-type orbitals (STOs), does not seem to influence the field gradient, provided the basis set is large enough.<sup>63</sup> For this reason, the computationally more efficient GTOs are usually preferred to STOs, which give a better representation of the cusp of the charge density at the nucleus. Since relativistic calculations give no significant improvement of the calculated electric field gradients,<sup>66</sup> most of the reported EFG calculations have been performed with nonrelativistic methods.

### 3.10.3 Isomer Shift

According to equation (8), the absolute value of the isomer shift,  $\delta_{\text{abs}}$ , depends linearly on the electronic charge densities  $\rho_S(0) = e|\varphi(0)_{\text{source}}|^2$  and  $\rho_A(0) = e|\varphi(0)_{\text{absorber}}|^2$  at the Mössbauer nuclei in the source and in the absorber, respectively.<sup>67</sup> Usually, nonrelativistic electronic structure calculations are performed, giving an electronic charge density  $\rho_{\text{nr}}(0)$  that is smaller than the true value (nonrelativistic  $\sim 1.2 \cdot 10^4$  au as compared to relativistic  $\sim 1.5 \cdot 10^4$  au in case of  $^{57}\text{Fe}$ ). Fortunately, the relativistic charge density  $\rho(0)$  can in good approximation be retrieved from the nonrelativistic charge density  $\rho_{\text{nr}}(0)$  by multiplication with a so-called relativity factor  $S(Z)$ :

$$\rho(0) = S(Z)\rho_{\text{nr}}(0) \quad (22)$$

This factor is about 1.32 in the case of iron and about 2.48 in the case of tin. One may conclude that—like for the quadrupole splitting—for the prediction of the isomer shift also nonrelativistic calculations are fully sufficient. Since it is quite difficult to determine the absolute isomer shift as defined in equation (8), it is common practice to give the isomer shift as the difference,  $\delta = \delta_{\text{abs, sample}} - \delta_{\text{abs, standard}}$ , compared to a given standard (e.g.,  $\alpha$ -iron foil or sodium nitroprusside in case of iron). In principle, one could try to predict the isomer shift directly, using equation (8) and the relativity factor  $S(Z)$ . However, it turns out that the accuracy of the calculated charge densities as well as the accuracy of the experimentally observed radii of the Mössbauer nuclei in the ground and excited state is not sufficient for this approach. Therefore, it is common to use linear regression on a large data set containing measured isomer shifts and calculated charge densities. For this purpose, the isomer shift can be written as

$$\delta = \alpha[\rho_{\text{A,nr}}(0) - b] \quad (23)$$

where  $\alpha$  and  $b$  are parameters that have to be determined by linear regression. A large number of studies have been performed to estimate  $\alpha$  and  $b$  by semiempirical molecular orbital, ab initio and DFT calculations, first for free atoms<sup>68–73</sup> (see also Ref. 74 for a review), and also later for molecules.<sup>64,65,75–79</sup> A detailed description of the technical details of the calculation of charge densities and an extensive review of previously published work on this subject have been given by Neese.<sup>80</sup>

With increasing computational resources, the correlation between calculated charge densities and measured isomer shifts has improved significantly. A benchmark for the calibration of the parameters  $\alpha$  and  $b$  in equation (24) has been given by Neese,<sup>80</sup> who compiled data for 15 iron-containing compounds that cover a range of the isomer shift from  $-0.87 \text{ mm s}^{-1}$  to  $+1.39 \text{ mm s}^{-1}$ . The linear regression of the measured isomer shifts with respect to nonrelativistic charge densities calculated with B3LYP gives a remarkable correlation and a standard deviation between measured

**Figure 20** Calibration of the B3LYP method for the prediction of  $^{57}\text{Fe}$  isomer shifts. The calculated electron density at the iron nucleus is plotted versus the experimentally determined isomer shift for a series of 15 iron-containing compounds. (Reprinted from Neese,<sup>80</sup> © 2002, with permission from Elsevier)

and predicted isomer shifts of about  $0.1 \text{ mm s}^{-1}$  (Figure 20). Similar results were obtained with the BP86 method.<sup>80</sup>

It is important to note that, although different DFT and ab initio methods can be used for the prediction of the isomer shift with comparable accuracy, these methods nevertheless give quite different values for the charge densities at the Mössbauer nucleus. The linear regression parameters  $\alpha$  and  $b$  obtained with a particular method are therefore not useful for charge densities that have been calculated with any other method.

There is a long-standing tradition to correlate the measured isomer shifts with calculated orbital populations of the Mössbauer isotope, especially with the populations of the valence orbitals. The first reason for this tradition is the restricted computational resources that did not allow full electron basis sets. A second reason is the intention to rationalize the relation between physical and chemical concepts like spin and oxidation state of the Mössbauer atom. While the first argument is becoming obsolete even for large bioinorganic molecules, the second argument is as appealing as ever, since the prediction of isomer shifts by DFT methods has to some extent the character of a ‘black box’, despite its remarkable accuracy. However, the correlation of orbital populations and isomer shifts is hindered by several problems. The first problem is that orbital populations may significantly depend on the basis set employed. A second problem is that the relation between the orbital populations and the charge density at the nucleus is fairly complex since core and valence orbitals change their shape owing to shielding and covalency effects. An authoritative analysis of these complex relations has been given by Neese.<sup>80</sup> Vrajmasu *et al.* have combined DFT calculations with a semiempirical model that is able to predict the influence of redox states on the isomer shift in iron proteins.<sup>81</sup>

Instructive examples for the possible benefit of isomer shift calculations using DFT are some recently

investigated high-valent iron complexes like those that are described in Sections 3.7 and 3.8. For instance, the Fe(VI) complex  $[(\text{Me}_3\text{cy-ac})\text{FeN}](\text{PF}_6)_2$ , reported by Berry *et al.*<sup>55</sup> (see also Section 3.8), exhibits a surprisingly high isomer shift. For this reason, a series of similar complexes with different electronic configuration was investigated by spectroscopic and by theoretical methods in order to confirm the oxidation state VI of this complex. DFT calculations were able to accurately reproduce the spectroscopic results for the investigated series of complexes and they confirmed that the electronic configurations that have been assigned to the complexes as a result of the spectroscopic data were consistent with the calculated electronic structures.

#### 3.10.4. Lamb–Mössbauer Factor

The Lamb–Mössbauer factor  $f_{\text{LM}}$ , which is difficult to determine experimentally as well as computationally, does not belong to the most common Mössbauer parameters in the field of inorganic chemistry. It can be of importance, however, when Mössbauer spectra are used to determine for a given sample the fractions of different species containing the same Mössbauer isotope. This is the case, for instance, for iron spin-crossover complexes where Mössbauer spectroscopy can be used to measure the temperature- or pressure-dependent fraction of different spin isomers.<sup>82</sup> The first approach to estimate the change of the Lamb–Mössbauer factor upon spin crossover has been restricted to molecular vibrations, neglecting the important contribution that arises from intermolecular vibrations.<sup>83,84</sup>

#### 3.10.5 Spin Hamiltonian Parameters

In case of paramagnetic compounds in high magnetic fields, it is common to use the spin Hamiltonian formalism to interpret the Mössbauer spectra (compare Section 2.3.4). This formalism employs adjustable parameters like the  $g$  tensor, the hyperfine coupling tensor  $\vec{A}$ , the zero-field  $D$  splitting, and the rhombicity  $E/D$ , in order to simulate the measured spectra. The interpretation of these parameters in terms of geometric and electronic structure can be supported by DFT calculations. In general,  $g$  tensors can be calculated quite accurately by DFT methods. Unfortunately, in the case of transition metal complexes sometimes only qualitative agreement can be achieved. Currently, the best results seem to be obtained by a combination of nonrelativistic DFT methods and second-order perturbation theory.<sup>85</sup> The calculation of the hyperfine coupling tensor  $\vec{A}$  (consisting of the Fermi-contact contribution, a spin dipolar contribution, and an orbital contribution) of iron is currently less advanced than the  $g$  tensor. The first results have been published by Neese.<sup>85</sup> In the meantime, algorithms for the calculation of the hyperfine coupling tensor are implemented in many quantum chemistry program packages. A recent application to an oxoiron(IV)

complex is described in Ref. 52. In order to calculate the zero-field splitting  $D$  and the rhombicity  $E/D$ , the ground state wavefunction has to be mixed with wavefunctions of different multiplicities. This has first been achieved at the semiempirical level.<sup>86</sup> Only recently, very accurate calculations of the zero-field splitting using DFT have been presented.<sup>87–89</sup> While the zero-field splitting parameter  $D$  is currently systematically underestimated by DFT calculations,<sup>87,88</sup> more accurate results have been obtained by ab initio methods.<sup>90</sup>

#### 4 ACKNOWLEDGMENTS

We would like to dedicate this contribution to our academic teacher Ali Trautwein, who introduced us to the fascinating field of Mössbauer spectroscopy.

#### 5 END NOTE

- <sup>a</sup>. In the older literature isomer shifts are often reported relative to  $\text{Na}_2[\text{Fe}(\text{CN})_5\text{NO}]$  (Table 2) sodium nitroprusside. The values are related by  $\delta_{\text{NP}} = \delta_{\alpha-\text{Fe}} + 0.26 \text{ mm s}^{-1}$ .

#### 6 ABBREVIATIONS AND ACRONYMS

CEMS = conversion electron Mössbauer spectroscopy; DFT = density functional theory; EFG = electric field gradient; EPR = electron paramagnetic resonance; ESEEM = electron spin echo envelope modulation spectroscopy; GTO = Gaussian-type orbitals; hTH = human tyrosine hydroxylase; MIMOS = miniaturized mössbauer spectrometer; NFS = nuclear forward scattering; NMR = nuclear magnetic resonance; RFQ = rapid freeze quench; SAM = *S*-adenosyl-L-methionine; SCC = self-consistent charge; STOs = slater-type orbitals; TMP = tetramesitylporphyrin; XAS = X-ray absorption spectroscopy.

## Abbreviations

CoA = Coenzyme A; CoM = Coenzyme M, 2-thioethane-sulfonate; ENDOR = Electron nuclear double resonance; EPR = Electron paramagnetic resonance; H<sub>4</sub>MPT = Tetrahydromethanopterin; HS-HTP = N-7-mercaptoheptanoyl-O-phosphothreonine; MCR = Methyl-CoM reductase; MRF = Methyl-reducing factor; XAS = X-ray absorption spectroscopy; GSH = Glutathione.

## 1 INTRODUCTION

The nickel enzymes covered in this article can be divided into two groups: redox enzymes and hydrolases. The five Ni redox enzymes are hydrogenase, CO dehydrogenase (CODH), acetyl-CoA synthase (ACS), methyl-Coenzyme M reductase (MCR), and superoxide dismutase (SOD). Glyoxalase-I and urease are Ni hydrolases. Ni proteins that are not enzymes are not covered, because they have been recently reviewed.<sup>1,2</sup> These include regulatory proteins (NikR) and chaperonins and metal uptake proteins (CooJ, CooE, UreE, and ABC transporters). A recent crystal structure of NikR, shown in Figure 1(i), is a notable recent achievement in this area.<sup>3</sup>

## 1.1 Biology of Nickel

Derived from the German word meaning Devil's copper, Ni is an essential element that, at elevated levels, is toxic, causing skin allergies, lung fibrosis, and cancer of the respiratory tract (see *Metal Ion Toxicity*).<sup>10,11</sup> While the total Ni concentration in most natural environments is in the low nM range (e.g. ~20 nM in freshwater or seawater and 0.5 nM in the human bloodstream),<sup>12</sup> industrial workers like welders are exposed to atmospheric Ni levels that have been determined to be a cancer risk ( $>1 \text{ mg m}^{-3}$ ). Ni becomes toxic at relatively high levels (oral LD50 in rats for nickel acetate =  $350 \text{ mg kg}^{-1}$ ). Based on studies of Ni depletion in rats as early as 1920, it was suggested that Ni is an essential element for higher animals;<sup>11</sup> however, the source of the Ni requirement has not yet been uncovered. Following the initial discovery of a microbial Ni requirement for hydrogenase activity in 1965,<sup>13</sup> a Ni requirement for many microbes as an essential prosthetic group in key enzymes has been described. The diverse structures of Ni active sites are shown in Figure 1 and summarized in Table 1. Some general properties of the Ni enzymes are described in Table 2. Reviews on the bioinorganic chemistry of Ni are available.<sup>2,14</sup>

## 1.2 Chemistry of Nickel

Nickel (relative atomic mass = 58.69) is a first-row transition metal in group VIIIb of the periodic table. Although there are five natural isotopes, <sup>58</sup>Ni (68.3%) and <sup>60</sup>Ni (26.1%) are the most abundant. Proteins are often labeled with <sup>61</sup>Ni (nuclear spin, I, is 3/2) to identify the nickel site by EPR spectroscopy, since paramagnetic species with significant spin on <sup>61</sup>Ni exhibit a four-line splitting. <sup>63</sup>Ni, which is a beta emitter with a relatively long half-life of 100 years, can be used to identify Ni-containing proteins and to measure Ni uptake in cells.

Nickel can exist in oxidation states from 0 to +4 and all but the +4 state have been observed in biology. Although the 2+ state (3d<sup>8</sup>) is most common, the Ni redox enzymes described here appear to access either the 2+/1+ and/or the 3+/2+ redox couples. It has been proposed that the 0 state is important during catalysis by acetyl-CoA synthase. The hydrolases appear to only use Ni<sup>2+</sup>, which is a Lewis acid. Since Ni<sup>1+</sup> and Ni<sup>3+</sup> are paramagnetic, electron paramagnetic resonance (EPR) and related advanced methods like electron nuclear double resonance (ENDOR) and electron spin echo envelope modulation (ESEEM) are valuable spectroscopic methods used to study Ni redox enzymes. Some Ni enzymes have rather strong UV-visible and magnetic circular dichroism (MCD) bands that are redox- and coordination-dependent. X-ray absorption spectroscopic (XAS) methods are often used to assess the oxidation state and geometry of the Ni active site in proteins.

Ni<sup>2+</sup> generally adopts octahedral or tetragonally distorted octahedral geometry, but square-planar (diamagnetic) and tetrahedral (high-spin) geometries are well known. It forms tight complexes with histidine (log K<sub>f</sub> = 15.9), a property exploited in affinity tagging of engineered proteins for easy purification, and, among the first-row transition metals, is second only to Cu(II) in its ability to complex with acidic amino acids (log K<sub>f</sub> = 6–7).<sup>15</sup> Square-pyramidal and trigonal bipyramidal Ni<sup>2+</sup> complexes have also been reported. Ni<sup>1+</sup> generally contains distorted octahedral or square-planar geometry, while Ni<sup>3+</sup> is usually low spin, with distorted octahedral or trigonal bipyramidal geometry. Redox changes in Ni during redox activation and catalysis are

often accompanied by changes in the geometry and spin state.

## 2 UREASE (EC 3.5.1.5)

Urease, which catalyzes the reaction described by equation (1) (Table 1), was the first Ni enzyme to be identified.<sup>16</sup> A relatively recent review on urease is available.<sup>17</sup> Ironically, although urease was the first enzyme to be crystallized, it was not recognized at that time to be a metalloenzyme. A di-Ni hydrolase, urease catalyzes the

**Figure 1** Nickel centers in Enzymes. (a) dinuclear center of urease (1EJX). The two nickel ions are bridged by a hydroxide bridge and the two oxygens from K217\*, which is a carbamylated lysine residue. Each Ni ion binds an additional water ligand. (b) The dinuclear NiFe center of the reduced active state of the NiFe-Se hydrogenase from *desulfomicrobium baculatum* (1CC1).<sup>4</sup> The Se-Cys residue corresponds to C543 in *D. fructosovorans* and appears to be the general base in the heterolytic H<sub>2</sub> cleavage reaction. The Fe site contains 2 CN and 1 CO ligands. Besides the NiFe dinuclear center, this enzyme contains 3 [4Fe-4S] clusters. (c) The Ni tetrahydrocorphinoid active site of MCR (1HBN).<sup>5</sup> The oxygen from the side chain of glutamine-147 axially coordinates to the Ni. (d) The [2Ni-4Fe-4S] site of the *M. thermoacetica* ACS (1MJG).<sup>6</sup> A tetragonally distorted Ni ion, called the proximal Ni (Ni<sub>p</sub>) bridges the [4Fe-4S] cluster and the square-planar Ni, called the distal Ni (Ni<sub>d</sub>). Although Cu was present in the original structure, Ni has been shown to be the active metal at the Ni<sub>p</sub> site (see text). (e) The [Ni-4Fe-5S] site of the *C. hydrogenoformans* CODH (1JJY).<sup>7</sup> In the *R. rubrum* CODH, the sulfur from the homolog of C526 replaces the sulfide bridge in the Ni-Fe subsite (1JQK).<sup>8</sup> (f) The Ni active-site of *E. coli* glyoxylase-I (1F9Z) (g) The square-planar Ni active site of superoxide dismutase (1G0D). (h) The octahedral Ni site of aci-reductone dioxygenase (1M4O).<sup>9</sup> (i) The Ni-bound regulatory domain of NikR (1Q5Y).<sup>3</sup> The Ni ions are shown in cyan, sulfur in yellow, and iron in red

hydrolysis of urea to yield two moles of ammonia and carbonic acid. The ammonia can then serve as a nitrogen source. Urease also is a virulence factor that participates in GI tract infection by *Helicobacter pylori*. Urease is found in bacteria, plants, fungi, and invertebrates. Jack bean urease has a 545 kDa hexameric quaternary structure, with six identical 91 kDa subunits, while the *Klebsiella aerogenes* urease consists of three copies each of three smaller subunits (UreABC) (i.e. it is a homotrimer of the heterotrimeric unit), in which the larger UreC subunit (60.3 kDa) contains the dinuclear active site.

The structures of the ureases from *Klebsiella aerogenes*,<sup>18,19</sup> *Bacillus pasteurii*,<sup>20</sup> *H. pylori*,<sup>21</sup> and jack bean are known. The active site contains a dinuclear Ni–Ni center bridged by a carbamylated lysine residue and a hydroxy group (Figure 1(a)). Based on MCD and magnetic susceptibility measurements, the two Ni ions appear to be high spin Ni(II) ( $S = 1$ ) and become strongly antiferromagnetically coupled when the inhibitor  $\beta$ -mercaptoethanol is bound ( $J = -40 \text{ cm}^{-1}$ ).<sup>22</sup> Synthesis of this metallocenter is a multistep process that has been recently reviewed<sup>4,2</sup> in which several accessory proteins (UreDFG) form a complex with apourease (UreABC in bacteria like *K. aerogenes*) and promote assembly of the Ni ions into the urease apoenzyme by UreE, carbamylation of lysine with carbon dioxide, and GTP hydrolysis by UreG. In bacteria, the accessory proteins are encoded adjacent to the urease structural genes, and, in some organisms, the gene cluster contains a Ni permease. The following complexes have been characterized: UreABCD, UreABCDF, and UreABCDFG. UreE, whose structure is known,<sup>23,24</sup> appears to be the metallochaperone that donates Ni to apourease. UreE contains a metal-binding domain and a Hsp40 chaperone domain. In *H. pylori*, there is evidence that the hydrogenase accessory proteins HypA and HypB are involved in urease assembly.

What features of the active site are responsible for the  $10^{14}$ -fold rate enhancement over the uncatalyzed reaction?

Urease can hydrolyze 3500 molecules of urea per second.<sup>25</sup> The bridging electrophilic carbamate group on the modified lysine residue stabilizes the dinickel center, which appears to be mechanistically significant since the enzyme is only active when both Ni are present in the active site. The Ni<sub>2</sub> ion has a nearly perfect octahedral coordination while Ni<sub>1</sub> shows a slightly distorted square-pyramidal coordination. The two Ni are bridged by the carbamate of lysine and by a hydroxide bridge. A proposed bimetallic mechanism (Figure 2) is based on computational studies,<sup>26,27</sup> model studies,<sup>28</sup> on the 2.0 Å X-ray structure of the diamidophosphoric acid-inhibited form of the enzyme (regarded as a transition state analogue),<sup>20</sup> and the 1.85 Å structure of the phosphate-inhibited form.<sup>29</sup> It appears that urea binds in a bidentate manner based on the X-ray crystallographic structure of the DAP-inhibited urease and on computational studies as shown in Figure 2. The urea carbonyl group is expected to bind to the most electrophilic Ni<sub>1</sub> while one amino group of urea would coordinate to Ni<sub>2</sub>. The hydroxide bridge between Ni<sub>1</sub> and Ni<sub>2</sub> is apparently parallel to the bound urea, which would facilitate nucleophilic attack of the bridging hydroxide on urea carbonyl carbon atom to give a tetrahedral intermediate. Replacement of the hydroxide bridge by fluoride inhibits urease, suggesting that the bridging hydroxide is responsible for hydrolysis of urea. Either the bridging hydroxide or His320 would then protonate the leaving ammonia molecule. However, it remains possible that a metal bound water molecule (W2) would act as the nucleophile. Figure 2 shows attack by the bridging OH to generate an OH<sup>−</sup> nucleophile that attacks bound urea, liberating NH<sub>2</sub>, which is protonated by an active-site histidine residue (or perhaps the proton release to form ammonia, and carbamate, which spontaneously and nonenzymatically hydrolyzes to another mol of ammonia and carbonic acid. Alternatively, it has been suggested that one of the bound water molecules facilitates the hydrolysis of the first product, carbamate.

**Figure 2** Mechanism of urease. This proposed mechanism features binding of urea through its carbonyl group to one of the Ni ions, making the carbon subject to nucleophilic attack by the bridging hydroxide leading to liberation of NH<sub>2</sub>, which is protonated by H<sup>320</sup> to form ammonia, and carbamate, which hydrolyzes to another mole of ammonia and carbonic acid. The same mechanism with proton transfer from water (instead of histidine) to ammonia is another possibility. Another possibility would be urea binding in a monodentate manner with a terminal hydroxide on Ni2 as the nucleophile

### 3 NiFe HYDROGENASES (EC 1.12.1.2, 1.2.2.1, OR 1.18.99.1)

Marjory Stephenson and Leonard Stickland proposed the name in 1931 for the enzyme that catalyzes equation (1), the oxidation of H<sub>2</sub> gas (Reaction 2, Table 1).<sup>30</sup> Hydrogenases are essential and versatile components of microbial metabolism that can catalyze the consumption as well as the production of H<sub>2</sub> gas.<sup>31</sup> Hydrogenases have been recently reviewed.<sup>32,33</sup> Uptake hydrogenases generate energy by coupling H<sub>2</sub> oxidation to the reduction of terminal electron acceptors like oxygen, nitrate, sulfate, CO<sub>2</sub>, and fumarate. Hydrogenotrophic organisms catalyzing H<sub>2</sub> oxidation are important in the global carbon cycle because elevated H<sub>2</sub> levels inhibit the anaerobic biodegradation of biomass. On the other hand, evolving hydrogenases siphon off excess reducing equivalents by transferring electrons to protons. Hydrogenases also are key to the processes of interspecies H<sub>2</sub> transport and H<sub>2</sub> cycling, which have been studied in sulfate reducers that generate a proton gradient during growth on organic substrates in the presence of SO<sub>4</sub>.<sup>34</sup> Efficient utilization of H<sub>2</sub> is accomplished by growth of microbes growing syntrophically, for example, by fatty- and aromatic acid-degrading fermentative bacteria growing in syntrophic association with a hydrogen-using microbes.<sup>35</sup> This association is important because fatty/aromatic acid degradation is thermodynamically unfavorable only at very low H<sub>2</sub> concentrations (equation (1)).

Hydrogenases are classified into four categories: the NiFeSe, NiFe, Fe-only, and one represented by N<sup>5</sup>,N<sup>10</sup>-methylene tetrahydromethanopterin dehydrogenase that was previously thought to lack metals<sup>36</sup> but now has been shown to contain a metallic cofactor.<sup>37</sup> The immediate electron donors/acceptors are metalloproteins like ferredoxin or cytochromes or an organic cofactor, like NAD. When the natural electron acceptors are limiting, some metalloenzymes in their reduced states, like pyruvate:ferredoxin oxidoreductase and carbon monoxide dehydrogenase, can reduce protons to H<sub>2</sub>.<sup>38</sup> Nitrogenase also generates H<sub>2</sub> with each cycle of N<sub>2</sub> reduction. This review will focus on the Ni enzymes.

All [NiFe]-hydrogenases contain at least two subunits ('large' and 'small') of approximately 60 and 30 kDa, containing a nickel center and at least one [4Fe-4S] cluster. The active site of H<sub>2</sub> oxidation/reduction by the Ni hydrogenases, located in the large subunit, is shown in Figure 1(b). This binuclear NiFe center is coupled to a 'wire' within the small subunit which is usually composed of three Fe-S clusters. The enzyme from *Desulfomicrobium baculatum*, shown in Figure 1(b), contains 3[4Fe-4S] clusters, although 2[4Fe-4S] and one [3Fe-4S] clusters are frequently observed. The hydrogenase shown here is a member of the subclass of the nickel-hydrogenases that contain a selenocysteine ligand.

Besides the reactions described above, hydrogenases also catalyze hydrogen isotope exchange, for example, between <sup>1</sup>H<sub>2</sub> gas and deuterium oxide (equation (2)) and interconversion of *ortho*- and *para*-hydrogen.<sup>39</sup> These reactions are expected to proceed through a metal-hydride intermediate, as first proposed in 1959 based on studies of the H-D exchange reaction using D<sub>2</sub> and H<sub>2</sub>O.<sup>40</sup> It is now generally accepted that hydrogenase catalyzes heterolytic cleavage of H<sub>2</sub> (equation (3)) followed by electron transfer to an external acceptor (equation (4)).<sup>41</sup> Electron transfer from the bound hydride to an external electron carrier protein is believed to be the function of the FeS clusters, which form an intramolecular 'wire'.

The structure of the catalytic center of the NiFe hydrogenase is shown in Figure 1(b). X-ray crystallographic studies showed that the Fe site of the binuclear NiFe center contains three nonexchangeable diatomic ligands<sup>42</sup> that were identified as one CO and two cyanide ligands by FTIR spectroscopy,<sup>43</sup> and assigned in the structure by their interaction with the protein (hydrogen bonds in the case of CN, a hydrophobic pocket in the case of CO).<sup>42,43</sup>

EPR spectroscopic studies have uncovered various redox states of the Ni hydrogenases (Scheme 1). The oxidized state of the [Ni]-hydrogenases exhibit EPR signals (called Ni-A and Ni-B) that disappear on reduction and have been attributed to the Ni<sup>3+</sup> oxidation state, with a (d<sub>z</sub><sup>2</sup>)<sup>1</sup> ground state (see *Splitting, Crystal Field & Molecular Orbital*).<sup>44</sup> The states of the enzyme that elicit these signals are called Form A and Form B. Neither Form A (an already oxidatively inactivated form) nor Form B is catalytically active, and neither is sensitive to inactivation by O<sub>2</sub>, indicating that both are oxidized forms.

**Scheme 1** The states of hydrogenase described here. Only the Ni-C\* and Ni-R states appear to be in equilibrium with H<sub>2</sub>. This scheme is revised from Ref. 49

Form A has been called the unready state ( $\text{Ni}_u$ ) because it requires prolonged treatment with a reductant (like  $\text{H}_2$ ) to undergo conversion to an EPR-silent state called  $\text{SI}_r$  (where the 'r' designates 'ready'), which is in redox equilibrium with Form B. Apparently this is a self-activation that occurs by electron transfer from the small amount of active enzyme present in the solution. An oxidizing agent is required to oxidize  $\text{SI}_r$  to Form B, indicating that Form B contains a  $\text{Ni}^{3+}$  state and  $\text{SI}_r$  contains a  $\text{Ni}^{2+}$  state. Form A and B are not in equilibrium; Form A must be reduced and reoxidized to convert it to Form B.  $\text{SI}_r$  is in equilibrium with  $\text{SI}_a$ , which is an active form that can be reduced to Form C, another EPR-detectable state, called Ni-C.

In the Ni-A state, the binuclear center appears to contain a hydroxide ligand that points toward a gas channel.<sup>45</sup>  $\text{H}_2$  treatment generates an EPR-detectable species (Ni-C) that appears to contain a bound state of hydrogen, based on ENDOR and ESEEM spectroscopy.<sup>46</sup> ENDOR studies demonstrate that an  $\text{OH}^-$  ligand bridges the Ni and Fe sites in the Ni-A and Ni-B states and is lost upon reduction to the Ni-C state.<sup>47</sup> This is consistent with XAS<sup>48</sup> and electrochemical<sup>49</sup> studies indicating that a hydroxo ligand present in Form A, Form B and  $\text{SI}_u$ , is removed during activation at the  $\text{SI}_r$  level. Photolysis of the Ni-C state at low temperatures alters its EPR signal to form the Ni-L state at a rate that is six-fold slower when  $^2\text{H}_2$  is used.<sup>50</sup> Ni-C forms and decays to an EPR-silent state at rates consistent with its involvement in catalysis.<sup>51</sup> The properties just described indicate that Ni-C is an intermediate state in the catalytic cycle. Although whether or not Ni-C contains a hydride species remains controversial, single-crystal EPR studies were interpreted to indicate that Ni-C can be described as a Ni(III) species with a bridging hydride between the Ni and the Fe atoms and that the photolysis product, Ni-L, is a Ni(I) species with a proton removed from the bridging position<sup>52</sup> or from one of the Cys ligands. If Ni-C does contain a hydride, perhaps it can be described in one of the following formulations:  $\text{Ni}^{\text{I}}\cdot 2\text{H}^+$ , or  $\text{Ni}^{\text{III}}\cdot \text{H}_2$ , or  $\text{Ni}^{\text{III}}\cdot \text{H}^-$ , although a Ni(I) state appears to be ruled out by XAS experiments.<sup>48</sup>

One of the shocking discoveries in the hydrogenase field was that the active site contains diatomic ligands, which were identified by IR spectroscopy.<sup>53</sup> The IR bands from the diatomic ligands are sensitive indicators of the state of the enzyme. In the Ni-A state of the *D. fructosovorans* [NiFe] hydrogenase, the CO stretching mode appears at  $1947\text{ cm}^{-1}$ , while the CN bands appear at  $2096$  and  $2084\text{ cm}^{-1}$ .<sup>54</sup> These bands appear at  $1938$ ,  $2060$ , and  $2074\text{ cm}^{-1}$  in the Ni-R state and at  $1951$ ,  $2074$ , and  $2086\text{ cm}^{-1}$  in the Ni-C state. These strong-field ligands are thought to maintain the Fe atom in the binuclear site in its low-spin ferrous state as indicated by Mössbauer spectroscopy.<sup>55</sup> This type of coordination appears to favor the binding of molecular hydrogen or hydride to the active site.

Besides identifying the tightly bound intrinsic CO and CN ligands to the Fe site of the NiFe center, IR studies provide

evidence that another CO can interact weakly with Ni in the reduced Ni-C state, which blocks both electron and proton transfer at the active site.<sup>54</sup>

The biosynthesis of all the [NiFe] hydrogenases, including the  $\text{H}_2$ -sensing regulatory protein,<sup>56</sup> requires the function of seven Hyp proteins (HypA, HypB, HypC, HypD, HypE, HypF, and HypX) to assemble the [NiFe] active site. Their functions and the assembly process has been reviewed.<sup>1,57</sup> Before Ni is incorporated, the  $\text{Fe}(\text{CO})(\text{CN})_2$  site appears to be assembled by HypD, E, and F, the diatomic ligands apparently derived from carbamoyl phosphate.<sup>58</sup> The other Hyp proteins, two of which are similar to UreE and UreG and a protease (HyaC, D, and I) are involved in Ni incorporation and maturation of hydrogenase to its active state.

$\text{H}_2$  accesses the active site through a tunnel in the protein,<sup>59</sup> where it forms a complex with the NiFe catalytic center buried  $30\text{ \AA}$  beneath the surface and then catalyzes heterolytic cleavage to form a Ni-hydride and a proton. Isotope effect studies indicate that electron transfer is rate limiting in  $\text{H}_2$  oxidation and proton transfer is rate limiting in proton reduction.<sup>60</sup> When the NiFe hydrogenase is absorbed to a pyrolytic graphite edge-plane (PGE) electrode and studied by voltammetric methods, the rate of  $\text{H}_2$  oxidation is diffusion-controlled ( $k_{\text{cat}}/K_m$  of  $10^8\text{--}10^9\text{ M}^{-1}\text{ s}^{-1}$ ), with a turnover number reaching  $9000\text{ s}^{-1}$  at  $30^\circ\text{C}$ ; thus the NiFe center has a similar catalytic activity to platinum.<sup>61</sup>

After binding and heterolytically cleaving  $\text{H}_2$ , the Ni-C state apparently is formed, which contains the bound hydride. One of the terminal cysteine ligands of the active-site nickel atom (the Se-Cys residue in Figure 1(b)) is considered to be the general base in the heterolytic cleavage reaction by binding the released proton. This conclusion is based on X-ray diffraction data, X-ray absorption spectroscopic studies, EPR, model complex studies, and theoretical calculations. A conserved glutamic residue (E25 in *D. fructosovorans* or E18 or *D. gigas*) that forms a hydrogen bond with this cysteine/selenocysteine residue<sup>62</sup> appears to be the first step in a proton transfer chain that couples the base catalyst to eventual proton release to the solvent.

A fifth type of hydrogenase is in the NiFe class, but is oxygen insensitive and has very low catalytic activity, functioning not as an enzyme, but as a hydrogen sensor.<sup>63</sup> Like the catalytic hydrogenases, this class of proteins contains two subunits encoded by *hupUV* in *Rhodobacter capsulatus* or *hoxBC* in *R. eutropha*). Remarkably, this protein has spectroscopic properties similar to the standard NiFe hydrogenase with 2 CN and 1 CO bound to the low-spin Fe site, indicating high structural homology between the two enzyme classes.<sup>64</sup> Why isn't this enzyme active? It apparently is blocked in the Ni-C state. Further reduction to the Ni-R is apparently required for catalytic turnover (above).<sup>64</sup> The regulatory mechanism involves interaction between the NiFe protein with histidine kinase and response regulator proteins, which modulate transcription of the hydrogenase-related genes.<sup>65</sup>

#### 4 CARBON MONOXIDE OXIDOREDUCTASES (CODH, EC 1.2.99.2)

CODH is at the heart of the ability of microbes to use CO as a sole carbon and electron source. CODH rapidly and efficiently oxidizes CO at rates between 4000 and 40 000 s<sup>-1</sup>, depending on the source, and reduces CO<sub>2</sub> (~11 s<sup>-1</sup>) with virtually no overpotential and under mild conditions. CO biochemistry and bioinorganic chemistry has been most thoroughly studied in enzymes from the anaerobic microbes, *Moorella thermoacetica*, *Rhodospirillum rubrum*, *Carboxydothermus hydrogenoformans*, and the aerobic carboxydobacterium, *Oligotropha carboxidovorans*. Only the anaerobic CODHs will be discussed here since the aerobic CODHs lack Ni and have a Mo-pterin active site (see **Molybdenum: MPT-containing Enzymes**). CODH and ACS have been the subjects of several reviews.<sup>66–68</sup>

There are two types of Ni-CODHs: one class is a homodimer and catalyzes only CO oxidation, while the other also contains acetyl-CoA synthase activity on a separate subunit. The *R. rubrum* CODH is encoded by *cooS*, which is part of the *coo* regulon consisting of at least two operons whose expression is induced at least 1000-fold when the microbe senses the presence of CO. CO is sensed and the *coo* gene cluster is regulated by the heme protein, CooA, which is a member of a large family of transcriptional activators that includes the cAMP regulatory protein (CRP) and fumarate nitrate regulatory protein (FNR).<sup>69</sup> The first operon in the *coo* gene cluster includes a NiFe hydrogenase and proteins just described that are involved in generating the mature enzyme, while the second operon consists of CODH (*cooS*), a membrane-associated electron transfer FeS protein (*cooF*), and genes involved in generating the NiFeS active site of CODH. Metal center assembly proteins include CooC, a Ni insertase similar to UreG, and CooJ, which is similar to UreE.<sup>70</sup> The proteins involved in Ni incorporation into CODH and their functions have been reviewed.<sup>71</sup>

The CODHs from *R. rubrum*, *C. hydrogenoformans*, and *M. thermoacetica* have been most extensively studied and structures are known for each of these proteins. All ligands at the active site, as well as some residues proposed to facilitate acid-base chemistry at the active site, are conserved among these proteins, even those that associated with ACS. The X-ray crystal structure of CODH reveals a mushroom-shaped homodimeric enzyme containing 5 metal clusters (Clusters B, C, and D).<sup>6–8,72</sup> Electrons generated during CO oxidation at the C-Cluster are transferred to a 'wire' consisting of the B-, a typical [4Fe–4S] cluster, and the D-Cluster, a [4Fe–4S] cluster with two cysteine ligands contributed by each subunit. As shown in Figure 1(e), the C-Cluster is a NiFe<sub>4</sub>S<sub>4–5</sub> cluster that can be viewed as a [3Fe–4S] cluster bridged to a binuclear NiFe center. Controversy remains about whether the Ni and Fe are bridged by a sulfide or by a cysteine sulfide (C526 in *C. hydrogenoformans*). Adopting a distorted five-coordinate geometry with 4S and another unidentified ligand, the Ni site

is part of the cube. In the *C. hydrogenoformans* structure, all 4Fe atoms are bridged to Ni through inorganic sulfide ligands, with Ni–Fe distances distributed over 1 Å (2.8, 2.9, 3.3, and 3.7 Å),<sup>7</sup> while in the 2.8 Å resolution structure of CO-treated Rr-CODH,<sup>8</sup> all four Ni–Fe distances are clustered within a much tighter range between 2.6 and 2.8 Å and the external Fe is bridged to the Ni by a cysteine S ligand. Ni EXAFS studies of 'as-isolated' and CO-treated *C. hydrogenoformans* CODH indicate that CO treatment and/or reduction induces a major structural rearrangement of the C-Cluster to adopt a conformation similar to that observed in the *R. rubrum* structure.<sup>73</sup>

Like the NiFe center of hydrogenase, the C-Cluster exists in several redox states, including C<sub>ox</sub>, C<sub>red1</sub>, C<sub>int</sub>, and C<sub>red2</sub>. C<sub>red1</sub> and C<sub>red2</sub> can be observed by EPR spectroscopy. The [3Fe4S] component is proposed to remain in the 1- redox state (2Fe<sup>2+</sup>/1Fe<sup>3+</sup>/4S<sup>-2</sup>) throughout most of the catalytic mechanism, except in the C<sub>red2</sub> and C<sub>int</sub> states where it undergoes 1 electron reduction to the 2- state (3Fe<sup>2+</sup>), with most of the redox changes occurring at the NiFe center (Figure 3).

The *C. hydrogenoformans* CODH can catalyze CO oxidation with a turnover number of 39 000 s<sup>-1</sup> and a *k*<sub>cat</sub>/*K*<sub>m</sub> of over 10<sup>9</sup> M<sup>-1</sup> s<sup>-1</sup>.<sup>78</sup> The first step in the CODH reaction is binding of substrates, CO and H<sub>2</sub>O or CO<sub>2</sub> and protons to Cluster C. Dobbek *et al.* described a hydrophobic CO channel in the COOH-terminal domain of ACS and a hydrophilic positively charged water channel that connects the surface and the C-Cluster in the *C. hydrogenoformans* CODH II.<sup>7</sup>

Then, after CO and water bind, it is proposed that the water molecule binds to a metal center, presumably Fe and perhaps in a bridging position. The active metal-hydroxide is then proposed to attack the M-CO complex to form M-COOH. Elimination of CO<sub>2</sub> and a proton would leave the C-Cluster two-electrons more reduced, presumably in the C<sub>red2</sub> state. Conversion of C<sub>red1</sub> to C<sub>red2</sub> occurs very rapidly, as studied by rapid quench EPR.<sup>75</sup> Several basic residues near the C-Cluster, including Lys563, His93, and His261 and several other histidine residues, described as a histidine tunnel, were proposed to participate in these acid-base reactions. The His tunnel leading from the active site to the surface is proposed to deliver protons that are liberated during the reaction to the solvent. C<sub>red2</sub> then transfers its electrons to the B and D clusters, which in turn reduce the external electron carriers. The scheme shown in Figure 3 indicates the existence of a diamagnetic form of the C-Cluster (C<sub>int</sub>)<sup>77</sup> as an intermediate in the reduction of the B and D clusters.

#### 5 ACETYL-CoA SYNTHASE (ACS) (EC 2.3.1)

ACS catalyzes the synthesis of acetyl-CoA from CO, CoA, and a methyl group donated by a methylated corrinoid iron–sulfur protein (Reaction 4, Table 1). In the CODH-only enzymes like CODHI and II from *C. hydrogenoformans* and *R. rubrum*, there is evidence for a channel between the surface and the C-cluster (above). On the other hand, in CODH/ACS,

**Figure 3** Proposed CODH mechanism. This mechanism proposes that the active state is Cred1, consistent with recent electrochemical studies,<sup>74</sup> which contains a bridging hydroxide at the binuclear NiFe center that serves as the nucleophile to attack a Ni-bound carbonyl forming a Ni-carboxylate. This OH, which is formed by acid-base catalysis by indicated acid-base residues, is in the position of the bridging sulfide in the *C. hydrogenoformans* structure.<sup>7</sup> The enzyme is proposed to remain in the Cred1 redox state until formation of CO<sub>2</sub> when it becomes two-electrons reduced to the Cred2 state. Conversion of Cred1 to Cred2 occurs faster than electron transfer from Cred2 to the FeS clusters,<sup>75,76</sup> which in turn reduce external electron acceptors. The electron transfer reactions are proposed to occur through a diamagnetic Cint state.<sup>77</sup>

such a channel would be detrimental, since the purpose of these proteins is to generate CO from CO<sub>2</sub> and utilize the CO in acetyl-CoA synthesis. Accordingly, there is both biochemical<sup>79,80</sup> and structural<sup>6,72</sup> evidence for a CO channel or tunnel between the C-Cluster in the CODH subunit and the A-Cluster in the ACS subunit. Such a channel would couple CO production to its utilization, explain why only very low levels of CO escape during growth of acetogenic bacteria, and protect host organisms that harbor the microbes from being exposed to potentially toxic CO levels.

The X-ray crystal structures of ACS both free<sup>81</sup> and bound to CODH<sup>6,72</sup> are available. The active site, called the A-Cluster, is present in a domain that is most distant from the interface with the CODH subunit separating the A- and C-Clusters by over 75 Å. The A-Cluster (Figure 1(d)) consists of a [4Fe-4S] cluster bridged to a Ni site (Ni<sub>p</sub>) that is bridged by a cysteine thiolate to another Ni ion in a square-planar thiolato- and carboxamido-type N<sub>2</sub>S<sub>2</sub> coordination environment. The distal site resembles the mononuclear Fe site of nitrile

hydratase in which two Cys side chains and two backbone N atoms coordinate the Fe with a Cys-X-Cys motif.<sup>82</sup> Thus, one can describe the A-Cluster as a binuclear NiNi center bridged to a [4Fe-4S] cluster, similar to the Fe-only hydrogenases in which a Cys residue bridges a [4Fe-4S] cluster and a binuclear Fe site. The distal Ni atom is coordinated by the side chains of two Cys residues and by two backbone N atoms. When CO binds to CODH/ACS, an EPR signal, called the NiFeC signal is elicited, which appears to reflect the active state of the enzyme.

There has been controversy about the metal occupying the proximal metal center. In one structure, Cu was in high occupancy,<sup>6</sup> while, in another structure, Ni was in one molecule and Zn in the other.<sup>72</sup> There was evidence that the CuNi enzyme is active,<sup>6,83</sup> however, several papers insisted that only the NiNi form is active.<sup>72,81,84-86</sup> Recent spectroscopic, enzymatic, and computational studies provide further evidence that the NiNi enzyme is active and that the CuNi and ZnNi forms are not.<sup>87</sup>

A longstanding problem in studies of ACS are the heterogeneous composition of the protein, with only 20–30% activity, reflected in the intensity of the NiFeC EPR signal, described above. After recognition that the vulnerability of the proximal metal site in the A-Cluster to substitution with different metals underlies this heterogeneity, a protocol was developed in which a  $\text{Cu}^{+1}$ -specific chelator is used to remove the Cu and Ni is added to reconstitute the di-Ni center,

resulting in nearly homogeneous preparations of ACS with a NiFeC signal intensity of  $\sim 0.8$  spins per mol.<sup>87</sup> Recent DFT calculations<sup>88</sup> indicate that the NiFeC signal derives from a  $[\text{4Fe-4S}]^{2+}$  (net  $S = 0$ ) cluster bridged to a  $\text{Ni(I)} (S = 1/2)$  at  $\text{M}_p$  that is bridged to square-planar  $\text{Ni(II)} (S = 0)$  at  $\text{M}_d$ , with the spin predominantly on the Ni(I).

Figure 4 summarizes two proposed catalytic cycles for ACS. In a mechanistically related reaction sequence, called

**Figure 4** Proposed ACS mechanisms. The major difference between the two mechanisms is the oxidation state of the proximal Ni. In both cases, CO emerges from the channel and binds to the proximal metal of the A-Cluster to form a Ni-CO intermediate. Then, the Ni center performs nucleophilic attack on the methyl group of methylated CFESP to form a (CH<sub>3</sub>)(CO) intermediate state of the A-Cluster. Then, carbon-carbon bond formation occurs by condensation of the methyl and carbonyl groups to form an acetyl-metal species. Finally, CoA binds to cleave the acetyl group as acetyl-CoA. See text for more details

the Monsanto or Reppe process, a rhodium complex catalyzes acetate formation from methanol and CO in the presence of HI through methyl-Rh, Rh-CO, and acetyl-Rh organometallic intermediates. ACS catalyzes the final steps of a biological process called the Wood–Ljungdahl pathway in which a methyl group, CO, and CoA are condensed to form acetyl-CoA at the A-Cluster of ACS. Although it also has been proposed that the methylation precedes carbonylation,<sup>89</sup> the first step in both reaction sequences proposed here is the binding of CO, emerging from the protein channel, to the A-Cluster to form a Ni–CO intermediate. In the top mechanism, the carbonylated enzyme is a  $\text{Ni}^{1+}$ -CO intermediate, the NiFeC species, which has been characterized by IR<sup>90,91</sup> and EPR<sup>92</sup> spectroscopy and has been shown to be catalytically competent in the pathway.<sup>93</sup> In the bottom mechanism, a diamagnetic  $\text{Ni}^0$  active enzyme has also been proposed.<sup>72</sup> The next step is nucleophilic attack of the A-Cluster on the methyl group of methylated CFeSP to form a methylated state of the A-Cluster.<sup>93</sup> This reaction generates a diamagnetic product, which is easily accommodated into the bottom mechanism; however, this would require a one-electron reduction to accompany methylation if a diamagnetic  $\text{CH}_3\text{--Ni}^{+2}$  species is the product. This is proposed to occur through an internal electron transfer reaction, which could involve the FeS cluster. Then, carbon–carbon bond formation occurs by condensation of the methyl and carbonyl groups to form an acetyl-metal species. Finally, CoA would bind and cleave the acetyl group as acetyl-CoA. This would liberate two electrons, which would regenerate the  $\text{Ni}^0$  state in the bottom mechanism. In the top mechanism, the electron transferred during the methylation would be returned and the other electron would be used to regenerate the  $\text{Ni}^{1+}$  active site. The overall reaction sequence is strongly inhibited by CO<sup>94</sup> and it appears that it is the methylation step that is inhibited.<sup>93</sup>

Based on the crystal structures, it is clear that the ACS subunit assumes two conformations: one in which the A-Cluster is inaccessible and the channel accessible to solvent and another in which the A-Cluster is accessible and the CO channel is inaccessible to solvent. Recent biochemical evidence indicates that major conformational changes occur during the catalytic cycle of acetyl-CoA synthesis.<sup>95</sup>

## 6 METHYL-COENZYME M REDUCTASE (MCR) (EC 2.8.4.1)

MCR catalyzes the final step in the biological synthesis of methane. Methanogenesis occurs in a unique group of microbes, called methanogens, which are members of the so-called third kingdom of life, the archaea. These organisms use very simple substrates as a source of carbon and energy, including  $\text{H}_2/\text{CO}_2$ , methanol, CO, methylamines, acetic acid, and methyl mercaptans. All biologically produced methane is the result of MCR activity and has reached a global emission rate of 560 million metric tons per year and a 2002 level of 1.75 ppm.

MCR catalyzes the conversion of methyl-coenzyme M (methyl-SCoM) and N-7-mercaptoheptanoylthreonine phosphate (CoBSH) to methane and the mixed disulfide CoBS-SCoM (Reaction 5, Table 1). Methanogenesis and MCR have both been reviewed fairly recently.<sup>96,97</sup> At the active site of MCR is Coenzyme  $\text{F}_{430}$  (Figure 1(c)), which is a nickel tetrapyrrole (specifically, a tetrahydrocorphin), exhibiting a maximum absorption at  $\sim 430$  nm in its  $\text{Ni}^{2+}$  state, making it bright yellow.  $\text{F}_{430}$ , like porphyrin, chlorophyll, and vitamin  $\text{B}_{12}$ , is derived from 5-aminolevulinic acid. The structure of free  $\text{F}_{430}$  was elucidated by X-ray crystallographic and NMR methods. It is the most reduced tetrapyrrole in nature, containing four conjugated double bonds linking Rings B, C, and D and one isolated double bond in Ring A. Based on X-ray crystallographic studies of the protein,  $\text{F}_{430}$  forms the base of a narrow well that accommodates the two substrates and shields the reaction from solvent.<sup>5</sup> The Ni site is ligated by the four tetrapyrrole N atoms, a side chain oxygen of a glutamine residue, and a sixth ligand that differs with the state of the enzyme. The structures of the inactive nickel (II) enzyme in complex with CoM and CoB ( $\text{MCR}_{\text{ox1-silent}}$ ) and in complex with the heterodisulfide CoM-S-S-CoB product ( $\text{MCR}_{\text{silent}}$ ) have been resolved at 1.16 Å and 1.8 Å resolution, respectively.<sup>98</sup>

Several states of MCR exhibit EPR signals. This includes  $\text{MCR}_{\text{red1}}$ , which is accepted to contain  $\text{Ni}^{1+}$  and is the active state of the enzyme. This assignment is well accepted based on the similarity of its UV-visible and EPR spectra with isolated  $\text{Ni}^{\text{I}}\text{F}_{430}$  and on DFT computations.<sup>99,100</sup> Several spectroscopic characteristics led to the hypothesis that red1 may also have undergone tetrapyrrole ring reduction; however, electrochemical,<sup>101</sup> and MCD and computational studies<sup>100</sup> demonstrate that this is incorrect – red1 retains the five double bonds present in the  $\text{Ni}^{2+}$  states. Another important form is  $\text{MCR}_{\text{ox1}}$ , which retains the basic symmetry of the red1 EPR signal and similar nitrogen hyperfine splitting constants. Recent computational studies indicate that the ox1 state should be described as a  $\text{Ni}^{2+}$  state coupled to a thiyl radical (formally equivalent to a  $\text{Ni}^{3+}$  state).<sup>100</sup>

EPR spectroscopic studies with  $^{33}\text{S}$ -labeled coenzyme M demonstrate that, when CoBSH and CoMSH are both present, the thiol group of CoMSH interacts with the Ni(I) of  $\text{F}_{430}$ .<sup>102</sup> Apparently, CoBSH is required for MCR to exhibit this interaction.

Steady-state kinetic and crystallographic studies support an ordered ternary complex mechanism in which first methyl-SCoM and then CoBSH must bind before methane is formed. Presteady-state kinetic studies indicate that CoBSH is required for even a single turnover of methane formation, suggesting that CoBSH is integrally involved in the steps leading up to cleavage of the C–S bond of methyl-SCoM.<sup>103</sup> This may indicate that CoBSH forms an adduct with methyl-SCoM (a methylsulfuranyl species) before the methyl group is cleaved or that CoBSH is an obligate proton donor for the reaction. In many proposed mechanisms, a methyl-Ni intermediate is

**Figure 5** Proposed MCR mechanism. See text for details

included based on studies demonstrating that the Ni(I) form of the pentamethyl ester of F<sub>430</sub> reacts with activated methyl donors (e.g. methyl sulfonium ions and methyl iodide) to yield methane through protonation of a methylnickel intermediate (see *Nickel: Organometallic Chemistry*).

Density functional calculations indicate that a methyl-Ni species could not be part of the catalytic cycle of methane formation; instead methane formation occurs through a radical mechanism (Figure 5) in which a methyl radical abstracts a hydrogen atom from CoBSH to form methane.<sup>104</sup> *Step 1* involves homolytic cleavage of the C-S bond of methyl-CoM to generate a methyl radical and a thiyl radical on CoM. The thiyl radical is then proposed to accept an electron from Ni(I) to generate Ni(II) and the CoM-S<sup>•</sup> thiolate. Negative charge on the thiolate is proposed to be stabilized by H bonding interactions from two active site tyrosine residues. In *Step 2*, the methyl radical is proposed to abstract a H-atom from CoBSH to form methane and a thiyl radical on CoB. This step should lead to inversion of stereochemistry at carbon. If so, the H-atom transfer to the methyl radical must occur before the methyl group has a chance to rotate in the active site. *Step 3* involves formation of a S-S bond between CoBS and CoMS<sup>•</sup>, to generate a disulfide anion radical, while *Step 4* involves reduction of Ni(II) to regenerate active Ni(I) F<sub>430</sub>, release of products, and binding of substrates.

## 7 SUPEROXIDE DISMUTASE (SOD) (EC 1.15.1.1)

SOD protects cells against the detrimental effects of superoxide, a reactive oxygen species, by catalyzing the conversion of superoxide to hydrogen peroxide and oxygen (Reaction 6, Table 1).<sup>105</sup> The dismutation reaction catalyzed

**Figure 6** SODs catalyze the formation of hydrogen peroxide and oxygen from superoxide in a two-step reaction in which the metal is first reduced and then reoxidized by superoxide

by SODs proceeds via a mechanism wherein the metal is first reduced and then reoxidized by superoxide (Figure 6). Since the potentials involved in the oxidation and reduction of superoxide at pH = 7 are  $-0.33$  and  $0.87$  V, respectively,<sup>106</sup> the metal center must have a redox potential between these extremes. Four types of SODs are known and are typically classed by their active-site metal composition: MnSOD, FeSOD, CuZnSOD, and NiSOD. The NiSOD, which has been identified in some *Streptomyces*<sup>107</sup> and cyanobacteria, has approximately the same catalytic rate constant as the CuZn enzyme, about  $10^9 \text{ M}^{-1} \text{ s}^{-1}$ .<sup>108</sup>

Like the NiFe hydrogenase, NiSOD is translated as a pro-protein that requires processing to become an active enzyme. While the large subunit of hydrogenase requires processing of the C-terminal, 14 residues must be cleaved from the N-terminal of Ni SOD to generate an N-terminal histidine residue. Because active NiSOD could not be obtained without correct N-terminal processing, Maroney developed a strategy for heterologous expression of the SOD as a C-terminal fusion with a leader sequence containing a cleavable his tag sequence.<sup>109</sup>

Based on the XAS and EPR spectral changes associated with the reduction of NiSOD, it appears that it is the  $\text{Ni}^{3+/2+}$  couple that is involved in superoxide disproportionation.<sup>110</sup> Spectroscopic studies indicated that the SOD active site could be either a mononuclear or a binuclear Ni site;<sup>110,111</sup> however, the X-ray crystallographic studies indicate a mononuclear Ni center (Figure 1(g)) that is coordinated by the N-terminal amino group of His1 and the amide nitrogen of Cys2, and the side-chain thiolate sulfurs of Cys2 and Cys6.<sup>112,113</sup> EPR and XAS studies indicate that the reduced  $2+$  state consists of a square-planar Ni ion that becomes square pyramidal in the  $3+$  state, as the side-chain ring nitrogen of His1 becomes a fifth ligand.<sup>111</sup> The existence of an axial nitrogen ligand in the five-coordinate Ni(III) state appears to be responsible for the nitrogen hyperfine splittings observed by EPR,<sup>110</sup> however, it is puzzling that the HIQ mutant still exhibited nitrogen hyperfine splittings. The sulfur ligands have been proposed to play a major role in poisoning the  $\text{Ni}^{3+/2+}$  redox couple in the appropriate range for catalyzing both the reduction and

**Figure 7** Mechanism of glyoxalase I in methylglyoxal degradation. See text for details

the oxidation of superoxide,<sup>110</sup> and may also play a role as a source of protons in catalysis.<sup>111</sup>

## 8 GLYOXALASE-I (EC 4.4.1.5)

Methylglyoxal, which is a toxic species produced by several cellular reactions including the misfiring of triosephosphate isomerase during glycolysis, is hydrolyzed by the two-component glyoxalase system (GlxI and GlxII). As shown in Figure 7, after glutathione (GSH) reacts nonenzymatically with methylglyoxal to form a hemithioacetal, GlxI, the Ni component, catalyzes an isomerization reaction forming S-D-lactoylglutathione, which is hydrolyzed to lactate and GSH by GlxII. Glyoxal is harmful because it forms covalent adducts with DNA and proteins.

Although the yeast and human glyoxalases are Zn-dependent enzymes, the *E. coli* enzyme is specific for Ni.<sup>114</sup> The Ni site exhibits octahedral Ni coordination (Figure 1(f)), which is similar to the Zn coordination environment in the human enzyme.<sup>115</sup> *Yersinia pestis*, among other pathogens, are predicted to contain a Ni-dependent glyoxalase-I species.<sup>116</sup>

A suggested mechanism (Figure 7) for the *E. coli* GlxI<sup>115</sup> based on the X-ray structure (Figure 1(f)) includes binding of substrate to displace one of the water molecules and Glu122, which would allow Glu122 to act as a general base to abstract a proton from the substrate, which would lead to formation of the enediolate intermediate still coordinated to the Ni ion. For the Zn enzyme, it was pointed out that displacement of the Glu122 from coordination with the metal would increase the  $pK_a$  of

the carboxyl group, while coordination of the substrate should decrease the  $pK_a$  of C1-H and that these combined effects would promote catalysis.<sup>117</sup> Reprotonation at C2 would form the product, which will then dissociate from the metal and leave the active site to serve as substrate for Glx2.

## 9 ACI-REDUCTONE DIOXYGENASE

During polyamine and ethylene biosynthesis, S-adenosyl-methionine (AdoMet) is converted to methylthioadenosine.

**Figure 8** Role of aci-reductone dioxygenase in methionine salvage

**Figure 9** Proposed mechanism of aci-reductone dioxygenase. See text for details<sup>9</sup>

Regeneration of AdoMet is accomplished by the methionine salvage pathway, which converts methylthioadenosine to methionine. Besides regenerating methionine, this pathway functions to control the concentration of methylthioadenosine, which is a powerful inhibitor of polyamine biosynthesis and transmethylation reactions.<sup>118</sup> A key intermediate in the methionine salvage pathway is 1,2-dihydroxy-3-keto-5-methylthiopentene (aci-reductone), which is oxidized to the  $\alpha$ -ketoacid precursor of methionine by aci-reductone dioxygenase (Figure 8). This dioxygenase catalyzes competing reactions, depending on its metal composition. The Fe-enzyme forms the methionine precursor, while the Ni enzyme generates methylthiopropionate, which is cytotoxic.

Aci-reductone dioxygenase folds into a beta-sandwich or jellyroll structure. The Ni active site (Figure 1(h)) is located at the loops connecting several of the beta sheets in a pseudo-octahedral environment consisting of oxygen and nitrogen ligands donated by the nitrogen atoms of three histidine residues, the oxygens from one glutamate residue, and the oxygens of two water molecules.

Figure 9 describes a proposed mechanism for the dioxygenase reaction based on enzymatic and structural studies.<sup>9,118</sup> It is proposed that the substrate binds as a dianion, which ligates the metal ion. Oxygen would then react to form an organic peroxide anion, which would then form a cyclic peroxide intermediate. The different reaction specificity is proposed to result from attack of the peroxide oxygen on alternative carbons. For example, the Ni-ARD would direct attack of the peroxide anion at the C3 carbonyl to form a five-membered peroxide intermediate, while the Fe-ARD would attack at carbon 2 to form a four-membered cyclic peroxide.

## Abbreviations

[9]aneN<sub>3</sub> = 1,4,7-triazacyclononane; [9]aneS<sub>3</sub> = 1,4,7-trithiacyclononane; cat = Catechol (1,2-dihydroxybenzene); dad = Diazadiene; EPR = Electron paramagnetic spectroscopy; imid = Imidazole; NMR = Nuclear magnetic resonance; pc = Phthalocyanine.

## 1 INTRODUCTION

Ni has the atomic number 28, atomic weight 58.69, and electron configuration [Ar]3d<sup>8</sup>4s<sup>2</sup>, and has five naturally occurring isotopes, <sup>58</sup>Ni 68.27%, <sup>60</sup>Ni 26.10%, <sup>61</sup>Ni 1.13%, <sup>62</sup>Ni 3.59%, and <sup>64</sup>Ni 0.91%. Ni is the 22nd most common element in the Earth's crust, with an estimated abundance of 99 ppm. The element was isolated in 1751 by A. F. Cronsted and named after the ore 'Kupfernickel'. Ni is widely distributed in silicate, sulfide, oxide, and arsenide ores; commercially important ores include garnierite, (Ni,Mg)<sub>6</sub>Si<sub>4</sub>O<sub>10</sub>(OH)<sub>8</sub>, limonite, (Fe,Ni)O(OH)·xH<sub>2</sub>O, and pentlandite, (Ni,Fe)<sub>9</sub>S<sub>8</sub>. The element is ferromagnetic and has a face-centered cubic structure.

## 2 GENERAL FEATURES

The literature on the coordination chemistry of Ni is immense, and this article can only summarize general

features and properties. Comprehensive reviews of the literature up to 1984 and up to 2002 have appeared,<sup>1,2</sup> while general summaries of Ni chemistry are given in inorganic textbooks<sup>3</sup> (see also *Nickel: Organometallic Chemistry* for descriptions of the organometallic and cluster chemistry of Ni).

The coordination chemistry of Ni features a very wide variety of mono- and polydentate ligands, with metal oxidation states ranging from 0 to +IV, although organometallic Ni<sup>-I</sup> and Ni<sup>-II</sup> species have been reported. The most common oxidation state by far is Ni<sup>II</sup>, although Ni<sup>0</sup> complexes are also well known. Ni<sup>I</sup> and Ni<sup>III</sup> species are less common, while Ni<sup>IV</sup> complexes are established only for certain ligand types. Table 1 summarizes typical data on the oxidation states and stereochemistries of Ni complexes. The basic electronic and spectral features of Ni complexes have been reviewed.<sup>4</sup>

### 2.1 Nickel(0)

Ni<sup>0</sup> complexes have a d<sup>10</sup> electron configuration and are typically stabilized by  $\pi$ -acceptor ligands such as PR<sub>3</sub>, CO, alkenes, N<sub>2</sub>, and CN<sup>-</sup>. Thus, bonding in Ni<sup>0</sup> species is usually highly covalent, with strong  $\pi$ -backdonation from the electron-rich metal center to the  $\pi$ -acceptor ligand orbitals. Many Ni<sup>0</sup> complexes are organometallic species (see *Nickel: Organometallic Chemistry*) and often have four-coordinate, tetrahedral geometries with an overall closed-shell 18-electron configuration, for example, [Ni(CO)<sub>4</sub>] (1) and [Ni(PF<sub>3</sub>)<sub>4</sub>] (2). With more bulky tertiary phosphine ligands, three-coordinate Ni<sup>0</sup> complexes can be prepared, for example, [Ni(PPh<sub>3</sub>)<sub>3</sub>] and [Ni(PCy<sub>3</sub>)<sub>3</sub>]. Square-planar adducts with O<sub>2</sub>, CO<sub>2</sub>, CS<sub>2</sub>, and SO<sub>2</sub> have also been reported; this stereochemistry maximizes orbital overlap between the metal center and the adduct molecule(s) and may also reflect a degree of oxidative addition at Ni<sup>0</sup> to afford a formal Ni<sup>II</sup> species. Ni<sup>0</sup> complexes are diamagnetic and generally highly reactive via oxidative-addition reactions to give octahedral Ni<sup>II</sup> products (see *Catalysis*).

### 2.2 Nickel(I)

Ni<sup>I</sup> complexes are relatively rare and are often stabilized by specialized ligands such as N-donor macrocycles and P-donor tripodal systems. Ni<sup>I</sup> has a d<sup>9</sup> electron configuration and its complexes are therefore paramagnetic with one unpaired electron. They show a variety of stereochemistries depending upon the ligands present, although four or five

**Table 1** Nickel complexes

| Metal oxidation state | Complex                                                                                                                                                                                                                                                                        |

| +3                    | $[\text{NiCl}_2(\text{[14]aneN}_4)]^+$ , $[\text{NiX}_3(\text{PR}_3)_2]$ , $[\text{Ni}(\text{[9]aneX}_3)_2]^{3+}$ (X = N, S)                                                                                                                                                   |
| +4                    | $[\text{NiF}_6]^{2-}$                                                                                                                                                                                                                                                          |

coordination is most common. Their general reactivity is based upon disproportionation to  $\text{Ni}^0$  and  $\text{Ni}^{\text{II}}$ , electron-transfer reactions, and dimerization to give diamagnetic metal–metal bonded products.

### 2.3 Nickel(II)

By far the most common oxidation state for Ni is the +II state with a  $d^8$  electron configuration. Four, five, and particularly six coordination are all common geometries for  $\text{Ni}^{\text{II}}$  and depend upon the ligands present. Scheme 1 shows the d-orbital splitting pattern for tetrahedral, square-planar, tetragonal, and octahedral  $\text{Ni}^{\text{II}}$ .

#### 2.3.1 Four Coordination

Four coordination for  $\text{Ni}^{\text{II}}$  is relatively common, with tetrahedral and square-planar geometries representing the two extreme possibilities. Good  $\pi$ -donor ligands such as halides tend to stabilize tetrahedral geometries, for example,  $[\text{NiCl}_4]^{2-}$  (3), while  $\pi$ -acceptor ligands such as  $\text{PR}_3$  and  $\text{CN}^-$  afford square-planar geometries, for example,  $[\text{Ni}(\text{CN})_4]^{2-}$  (4).

Tetrahedral complexes are usually highly colored (blue or green) with three expected d–d transitions,  ${}^3\text{T}_1(\text{F}) \rightarrow {}^3\text{T}_2(\text{F})$  ( $\nu_1$ ),  ${}^3\text{T}_1(\text{F}) \rightarrow {}^3\text{A}_2(\text{F})$  ( $\nu_2$ ), and  ${}^3\text{T}_1(\text{F}) \rightarrow {}^3\text{T}_1(\text{P})$  ( $\nu_3$ ), although the observed spectra tend to be complicated by spin–orbit coupling effects. Scheme 2 shows a simplified Orgel diagram (see Tanabe–Sugano Diagram) for tetrahedral and octahedral  $\text{Ni}^{\text{II}}$  complexes. The ligand field splitting parameter (see Ligand Field Theory)  $10Dq$  for the complexes  $[\text{NiX}_4]^{2-}$  varies from 4090, to 3790, to 3820  $\text{cm}^{-1}$  for X = Cl, Br, I, respectively. Tetrahedral  $\text{Ni}^{\text{II}}$  would be expected to have two unpaired electrons, and such complexes do indeed show experimentally temperature-dependent magnetic behavior with  $\mu_{\text{eff}}$  in the range 3.2 to 4.2 BM, consistent with a T ground-state for a  $e_g^4 t_{2g}^4$ .

**Scheme 1**

Scheme 2

configuration. The observed values of  $\mu_{\text{eff}}$  for these complexes are related to the degree of distortion from pure tetrahedral coordination.

Square-planar  $\text{Ni}^{\text{II}}$  complexes are typically yellow, red, or brown in color, and are invariably diamagnetic with a spin-paired configuration, although there is one report of paramagnetic planar  $\text{Ni}^{\text{II}}$  species.<sup>5</sup> Planar coordination for  $\text{Ni}^{\text{II}}$  is common and is linked to the stabilization of this geometry for  $d^8$  metal ions (see *Palladium: Inorganic & Coordination Chemistry* and *Platinum: Inorganic & Coordination Chemistry*). Typical examples of square-planar  $\text{Ni}^{\text{II}}$  complexes include  $[\text{Ni}(\text{CN})_4]^{2-}$  (4),  $[\text{Ni}(\text{dmgH})_2]$  (5),  $[\text{Ni}(\text{Me-salen})_2]$  (6) and  $[\text{Ni}(t\text{-Bu}_2\text{acac})_2]$  (7).

An interesting feature in four-coordinate  $\text{Ni}^{\text{II}}$  chemistry is the interconversion of paramagnetic, tetrahedral, and diamagnetic square-planar geometries.<sup>6</sup> Thus, complexes of the type  $[\text{NiX}_2(\text{PR}_3)_2]$  can be tuned towards one stereochemistry rather than another by variation of X (halide) and  $\text{PR}_3$  ligands. For example,  $[\text{NiCl}_2(\text{PPh}_3)_2]$  is tetrahedral, while  $[\text{NiBr}_2(\text{PET}_3)_2]$  is square-planar. Temperature-dependent equilibria between tetrahedral (blue or green) and square-planar (yellow or red) geometries are also seen for related complexes incorporating  $\text{PCy}_3$  and  $\text{PPh}_2\text{Bu}$  ligands. Moreover, in the solid-state structure of  $[\text{NiBr}_2(\text{PPh}_2\text{Bz})_2]$  both tetrahedral and square-planar forms are observed. These changes from tetrahedral to square-planar geometries are influenced by the steric bulk of the ligands, with tetrahedral coordination favored in general by highly bulky ligands.

Another common feature of square-planar  $\text{Ni}^{\text{II}}$  complexes is their ability to coordinate extra ligands in solution to set up equilibria between four-, five-, and six-coordinate complexes (equation 1). Thus, diamagnetic square-planar complexes can be transformed in coordinating solvents, or in the presence of extra ligands, to paramagnetic, octahedral  $\text{Ni}^{\text{II}}$  species. These transformations can be monitored by electronic spectroscopy. Aggregation of planar units can also occur in both solid state and solution, to form paramagnetic polymers. Thus,  $[\text{Ni}(\text{Me-salen})_2]$  forms dimeric and polymeric oligomers via bridging of the O-donor across planar units (8).<sup>7</sup> Another example is the structure of  $[\text{Ni}(\text{acac})_2]$  (9), which is actually trimeric with bridging acac ligands between octahedral, paramagnetic  $\text{Ni}^{\text{II}}$  centers.<sup>8</sup> Thus, in addition to tetrahedral  $\longleftrightarrow$  square-planar  $\longleftrightarrow$  five-coordinate  $\longleftrightarrow$  octahedral equilibria, monomer  $\longleftrightarrow$  oligomer/polymer equilibria may also exist for  $\text{Ni}^{\text{II}}$  complexes.

### 2.3.2 Five Coordination

Five-coordinate complexes usually incorporate polychelate or tripodal N-, P-, and As-donor ligands,<sup>9</sup> but are also observed in simpler systems such as  $[\text{Ni}(\text{CN})_5]^{3-}$  and  $[\text{Ni}(\text{PPhMe}_2)_3(\text{CN})_2]$ . Interestingly,  $[\text{Ni}(\text{CN})_5]^{3-}$  has been crystallized and characterized as a square-based pyramidal and a trigonal bipyramidal species; this is consistent with facile Berry rotation (*see Berry Pseudorotation*) interconverting square-based pyramidal and trigonal bipyramidal geometries in five-coordinate transition metal complexes.<sup>10</sup> Five-coordinate complexes can be paramagnetic (high spin,  $\mu_{\text{eff}} = 3.2\text{--}3.5$  BM), for example,  $[\text{NiBr}(\text{tren})]^+$  (**10**), or diamagnetic (low spin), for example,  $[\text{NiBr}(\text{NP}_3)]^+$  (**11**).

### 2.3.3 Six Coordination

Octahedral coordination is the most common geometry for  $\text{Ni}^{\text{II}}$  and is observed in a host of complexes with an extremely wide range of mono- and polydentate ligands, for example,  $[\text{Ni}(\text{L})_6]^{2+}$  ( $\text{L} = \text{H}_2\text{O}$ , py,  $\text{NH}_3$  (**12**)),  $[\text{Ni}(\text{LL})_3]^{2+}$

( $\text{LL} = \text{en}$  (**13**), bipy, phen), and  $[\text{Ni}(\text{terpy})_2]^{2+}$ . Three d-d transitions,  ${}^3\text{A}_{2g}(\text{F}) \rightarrow {}^3\text{T}_{2g}(\text{F})$  ( $\nu_1$ ,  $10Dq$ ),  ${}^3\text{A}_{2g}(\text{F}) \rightarrow {}^3\text{T}_{1g}(\text{F})$  ( $\nu_2$ ), and  ${}^3\text{A}_{2g}(\text{F}) \rightarrow {}^3\text{T}_{1g}(\text{P})$  ( $\nu_3$ ) (*see Scheme 2*), are expected for  $\text{Ni}^{\text{II}}$  in an octahedral field and these are usually observed. The value of  $10Dq$  varies as a function of ligand donor set, with values of 7730 for  $[\text{Ni}(\text{DMSO})_6]^{2+}$ , 8500 for  $[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$ , 10 750 for  $[\text{Ni}(\text{NH}_3)_6]^{2+}$ , 11 200 for  $[\text{Ni}(\text{en})_3]^{2+}$ , and 12 500  $\text{cm}^{-1}$  for  $[\text{Ni}([9]\text{aneN}_3)_2]^{2+}$ . The magnetic susceptibility of octahedral  $\text{Ni}^{\text{II}}$  is typically in the region  $\mu_{\text{eff}} = 2.9\text{--}3.3$  BM. Octahedral  $\text{Ni}^{\text{II}}$  ( $S = 1$ ) has a large zero-field splitting and so these complexes do not generally show EPR spectra, although paramagnetically shifted Nuclear magnetic resonance (NMR) spectra are observed in many cases.

### 2.3.4 Other Coordination

Three coordination is very rare and has been observed in sterically hindered phosphine and amide complexes of type  $[\text{Ni}(\text{PPh}_3)_3]$ ,  $[\text{Ni}(\text{NPh}_2)_3]^-$ , and  $[(\text{R}_2\text{N})\text{Ni}(\mu^2\text{-NR}_2)_2\text{Ni}(\text{NR}_2)]$ .<sup>11</sup> Seven coordination, although rare, is observed in pentagonal bipyramidal complexes incorporating pentadentate chelate and macrocyclic complexes, for example,  $[\text{Ni}(\text{14})(\text{L})_2]^{12}$  and  $[\text{Ni}(\text{15})(\text{L})_2]^{2+}$ .<sup>13</sup>

## 2.4 Nickel(III)

$\text{Ni}^{\text{III}}$  complexes have a  $d^7$  electron configuration [*cf.*  $\text{Co}^{\text{II}}$ ] and are usually five-coordinate or Jahn–Teller distorted octahedral species (*see Jahn–Teller Effect*) with characteristic EPR spectra.  $\text{Ni}^{\text{III}}$  is stabilized by halides, as in  $[\text{NiF}_6]^{3-}$  (**16**), and by strong  $\sigma$ -donor N- or P-ligands, as in  $[\text{Ni}([9]\text{aneN}_3)_2]^{3+}$  (**17**) and  $[\text{NiBr}_3(\text{PR}_3)_2]$  (**18**), and

is usually prepared by chemical or electrochemical oxidation of the  $\text{Ni}^{\text{II}}$  precursors.  $\text{Ni}^{\text{III}}$  is still a relatively rare oxidation state, although increasingly more examples are being reported, particularly with polyaza macrocyclic ligands.<sup>14</sup> More recently,  $\text{Ni}^{\text{III}}$  centres have been implicated in the activity of  $[\text{NiFe}]$ hydrogenase enzymes (see Section 8).

## 2.5 Nickel(IV)

$\text{Ni}^{\text{IV}}$  complexes have a  $d^6$  electron configuration and are invariably octahedral and diamagnetic. They are stabilized by strong  $\sigma$ - and  $\pi$ -donors such as halide, O- and N-donor oxime, amino acid, and amido ligands.  $\text{Ni}^{\text{IV}}$  species are very highly oxidizing and often transient species. Several complexes assigned originally as  $\text{Ni}^{\text{IV}}$  species have been reformulated as ligand-oxidized products.

## 3 NICKEL(0)

$\text{Ni}^0$  complexes are frequently highly reactive, air- and temperature-sensitive species, which undergo facile oxidative-addition reactions with a range of external substrates.

### 3.1 C-donor Complexes

The majority of  $\text{Ni}^0$  complexes are organometallic species incorporating CO and related  $\pi$ -acceptor ligands, the best known being the tetracarbonyl species  $[\text{Ni}(\text{CO})_4]$  (**1**). Related isocyanide and cyanide complexes such as  $[\text{Ni}(\text{CN}-t\text{-Bu})_4]$  and  $[\text{Ni}(\text{CN})_4]^{4-}$  have also been prepared. Both of these complexes are highly reactive and undergo substitution reactions with alkenes, alkynes, tertiary phosphines, CO, NO, and  $\text{O}_2$ .<sup>15</sup>  $[\text{Ni}(\text{CN}-t\text{-Bu})_2(\text{O}_2)]$  (**19**) is a highly reactive complex and shows a square-planar stereochemistry at Ni with the  $\text{O}_2$  ligand bound side-on (see *Side-on Coordination*).<sup>16</sup> The first stable complex of  $\text{CO}_2$ ,  $[\text{Ni}(\eta^2\text{-CO}_2)(\text{PCy}_3)_2]$ , has been structurally characterized. Such electron-rich  $\text{Ni}^0$  complexes undergo a host of oxidative coupling reactions with unsaturated organic molecules.<sup>17</sup> For an account of

organometallic complexes and clusters of Ni, see *Nickel: Organometallic Chemistry*.

### 3.2 N-, P-, As-, and Sb-donor Complexes

In general, N-donors are not sufficiently strong  $\pi$ -acceptors to stabilize low-valent states such as  $\text{Ni}^0$ . However, the diimine ligand **dad** can form stable tetrahedral  $\text{Ni}^0$  complexes  $[\text{Ni}(\text{dad})_2]$  (**20**).<sup>18</sup>

A wide range of  $\text{Ni}^0$  phosphine and arsine complexes,  $[\text{Ni}(\text{L})_3]$ ,  $[\text{Ni}(\text{L})_4]$  ( $\text{L} = \text{PR}_3$ ,  $\text{AsR}_3$ ,  $\text{SbR}_3$ ), and  $[\text{Ni}(\text{LL})_2]$  ( $\text{LL} = \text{chelate ligand}$ ), can be prepared by reduction of  $\text{Ni}^{\text{II}}$  precursors in the presence of excess phosphine and arsine ligands. Alternatively, ligand replacement on  $[\text{Ni}(\text{cod})_2]$  or directly on to nickel sponge affords the same products (equations 2–4).<sup>19</sup>

With bulky  $\text{PR}_3$  ligands, dissociation of ligand occurs to give the highly reactive  $[\text{Ni}(\text{PR}_3)_3]$  and even  $[\text{Ni}(\text{PR}_3)_2]$ .<sup>20</sup> A range of mixed  $\text{PR}_3$  and CO complexes  $[\text{Ni}(\text{CO})_{4-x}(\text{PR}_3)_x]$  ( $x = 1-4$ ) and alkene complexes  $[\text{Ni}(\text{PR}_3)_2(\text{alkene})]$  have been reported. The complex  $[\text{Ni}(\text{triphos})(\text{CO})]$  (**21**) and related tripodal complexes can be readily isolated by reduction of  $\text{Ni}^{\text{II}}$  precursors in the presence of CO and triphos;<sup>21</sup> the analogous nitrosyl complex  $[\text{Ni}(\text{triphos})(\text{NO})]^+$  (**22**) (NO is coordinated as  $\text{NO}^+$  in this complex) can be prepared by a similar route.<sup>22</sup> A wide range of related tetrahedral nitrosyl complexes of  $\text{Ni}^0$  incorporating bent NO,  $\text{NO}^-$ , and/or linear  $\text{NO}^+$  ligands have been synthesized (see *Nitrosyl Complexes*).<sup>23</sup>

Reaction of  $[\text{Ni}(\text{PR}_3)_4]$  or  $[\text{Ni}(\text{PR}_3)_2(\text{C}_2\text{H}_4)]$  with  $\text{O}_2$  affords the highly reactive species  $[\text{Ni}(\text{PR}_3)_2\text{O}_2]$  (**23**) which is related to the isocyanide complex (**19**).  $\text{Ni}^0$ -phosphine adducts of  $\text{CO}_2$  (**24**),<sup>24</sup>  $\text{CS}_2$  (**25**),<sup>25</sup> and  $\text{SO}_2$  (**26**)<sup>26</sup> can also be prepared,<sup>17</sup> while the formation of mononuclear  $\text{N}_2$  adducts has been proposed (equation 5).<sup>27</sup> The binuclear complex  $[\text{Ni}(\text{PCy}_3)_2]_2\text{N}_2$  (**27**) has been structurally characterized and shows a  $\mu^2$ -bridging  $\text{N}_2$  ligand,  $\text{N}-\text{N} = 1.12 \text{ \AA}$ , with the sterically bulky cyclohexyl groups stabilizing the general structure.<sup>28</sup>

The tripodal  $\text{Ni}^0$  complex  $[\text{Ni}(\text{NP}_3)]$  (**28**) can be prepared by reaction of  $\text{Ni}^{\text{II}}$  salts with  $\text{NP}_3$  in the presence of reducing agents such as  $\text{BH}_4^-$ .<sup>29</sup> A series of related tripodal  $\text{Ni}^0$  have been reported. The complex (**28**) and related tripodal species are highly reactive and add  $\text{H}^+$  to form complexes of the type  $[\text{Ni}^{\text{II}}\text{H}(\text{NP}_3)]^+$  (**29**), add  $\text{CO}$  to form  $[\text{Ni}(\text{NP}_3)\text{CO}]$  (**30**), and add  $\text{P}_4$  to form  $[\text{Ni}(\text{NP}_3)(\eta^1\text{-P}_4)]$  (**31**).<sup>30</sup> Related  $\text{P}_3$ - and  $\text{As}_3$ -bridged dimers  $[\text{Ni}_2(\text{triphos})_2(\text{P}_3)]^{2+}$  (**32**),  $[\text{Ni}_2(\text{triphos})_2(\text{As}_3)]^{2+}$ , and related mixed-metal complexes can be prepared by reaction of  $\text{Ni}^{\text{II}}$  salts with triphos in the presence of white phosphorus  $\text{P}_4$  or

yellow arsenic  $\text{As}_4$ .<sup>31</sup> The same reaction with  $\text{P}_4\text{S}_3$  and  $\text{As}_4\text{S}_3$  in place of  $\text{P}_4$  and  $\text{As}_4$ , respectively, affords the mononuclear species  $[\text{Ni}(\text{triphos})(\text{P}_3)]^+$  (**33**) and  $[\text{Ni}(\text{triphos})(\text{As}_3)]^+$ .<sup>32</sup> A fascinating complex  $[\text{Ni}(\text{P-}t\text{-Bu})_6]$  (**34**) containing a planar  $\text{P}_6$  ring has been reported from the reaction of  $\text{NiCl}_2$  with  $(\text{P-}t\text{-Bu})_3$ . By considering intramolecular  $\text{P}-\text{P}$  interactions,  $[\text{Ni}(\text{P-}t\text{-Bu})_6]$  can be regarded as an 18-electron species.<sup>33</sup>

#### 4 NICKEL(I)

In comparison with the relatively large number of  $\text{Ni}^0$  complexes that have been reported, relatively few  $\text{Ni}^{\text{I}}$  compounds

have been well characterized.  $\text{Ni}^{\text{I}}$  species are generally prepared via chemical or electrochemical reduction of  $\text{Ni}^{\text{II}}$  precursors, and are almost invariably highly reducing and air sensitive. They are often postulated as radical intermediates in electron-transfer reactions of  $\text{Ni}^0$  and  $\text{Ni}^{\text{II}}$  and have been implicated in the Ni-L form of [NiFe]hydrogenase. Mononuclear  $\text{Ni}^{\text{I}}$  species formally have a  $d^9$  electron configuration and have magnetic susceptibilities corresponding to one unpaired electron,  $\mu_{\text{eff}} = 1.7$  to  $2.3$  BM. Mononuclear  $\text{Ni}^{\text{I}}$  complexes are EPR active and often show  $g_{\parallel} > g_{\perp} > 2.0023$  for a  $(d_{x^2-y^2})^1$  ground-state configuration. The stereochemistries of  $\text{Ni}^{\text{I}}$  species vary from sterically hindered three-coordinate species, to four- and five-coordinate complexes. The chemistry of  $\text{Ni}^{\text{I}}$  complexes has been reviewed.<sup>14</sup>

#### 4.1 C-donor Complexes

Reduction of  $\text{K}_2[\text{Ni}(\text{CN})_4]$  with  $\text{K}/\text{NH}_3$  or  $\text{Na}/\text{Hg}$  affords  $\text{K}_2[\text{Ni}(\text{CN})_3]$ , which has been shown to be a  $\text{Ni}^{\text{I}}\text{--Ni}^{\text{I}}$  bonded

dimer  $[\text{Ni}_2(\text{CN})_6]^{4-}$  (35). The complex is diamagnetic with a Ni–Ni distance of  $2.32 \text{ \AA}$  and the  $\text{Ni}(\text{CN})_3$  units twisted by  $82^\circ$  to one another.<sup>34</sup>

#### 4.2 N-donor Complexes

Electrochemical reduction of  $[\text{Ni}(\text{bipy})_3]^{2+}$  affords  $[\text{Ni}(\text{bipy})_3]^+$  and  $[\text{Ni}(\text{bipy})_3]$ , which are formulated as  $\text{Ni}^{\text{I}}$  and  $\text{Ni}^{\text{I}}\text{--bipy}^-$  radical anion complexes, respectively.<sup>35</sup> These species are highly reactive and illustrate the problems of assigning redox products as genuine metal-based or ligand-based radicals.

A very wide range of tetraaza macrocyclic complexes of  $\text{Ni}^{\text{II}}$  have been prepared and studied. An important feature of many  $\text{Ni}^{\text{II}}$  macrocycles is their high stability and inertness. Macrocyclic ligands can therefore be regarded as protecting groups for the metal center, and this has led to the study of metal redox properties and the electrochemical generation of  $\text{Ni}^{\text{I}}$  products.<sup>36</sup> Some of the ligands that have been studied for  $\text{Ni}^{\text{I}}$  complexation are listed in Scheme 3.

The redox properties of the complexes (the reversibility and potential of the  $\text{Ni}^{\text{II/I}}$  couple) are related to the ring size, the donor atoms, the unsaturation, and the degree of functionalization of the macrocyclic ring. EPR spectroscopy has been particularly useful in differentiating between metal- and ligand-based radical species. Interestingly, the degree of alkylation at the N-donor ligands enhances the stabilization of  $\text{Ni}^{\text{I}}$  species by shifting the  $\text{Ni}^{\text{II/I}}$  couple to more anodic potentials; this effect has been ascribed to solvation and stereochemical effects.<sup>37</sup> Interestingly,  $\text{Ni}^{\text{I}}$  species can also be generated from pentagonal bipyramidal  $\text{Ni}^{\text{II}}$  precursors.<sup>13</sup> Reduction of the  $[\text{Ni}(\mathbf{36})]^{2+}$  by one electron affords a ligand-based radical species; addition of CO to these reduced solutions gives a metal-based  $\text{Ni}^{\text{I}}$  product  $[\text{Ni}(\mathbf{36})\text{CO}]^+$ , which has been assigned by EPR spectroscopy. This is an example of intramolecular electron transfer within a macrocyclic complex (equation 6).<sup>38</sup>

The single-crystal X-ray structures of macrocyclic  $\text{Ni}^{\text{I}}$  species showing square-planar coordination at the metal center have been reported. The complexes (37)<sup>39</sup> and (38)<sup>40</sup> both show  $\text{Ni}^{\text{I}}$  bound to four aza N-donors of a saturated macrocycle to give square-planar coordination at the metal center. The electrochemistry of a wide range of  $\text{Ni}^{\text{II}}$ –porphyrin complexes

### Scheme 3

has been investigated, particularly with regard to the formation of  $\text{Ni}^{\text{I}}$  and ligand-based ligand-radical anions.<sup>41</sup> The structure of a  $\text{Ni}^{\text{I}}$  complex of a modified porphyrin has been reported; in (39), one of the N-donors of the porphyrin has been replaced by an S-donor, with the resultant  $\text{SN}_3$ -donor ligand binding to  $\text{Ni}^{\text{I}}$  in a square plane. Interestingly, the S-donor acts as a long-range bridging ligand to another  $[\text{Ni}(\text{L})]$  unit to give an overall binuclear structure.<sup>42</sup>

A highly unusual air-stable  $\text{Ni}^{\text{I}}$  species has been produced using an interlocking catenane ligand (40). The  $\text{Ni}^{\text{II}}$  precursor

has an enforced tetrahedral geometry and shows a particularly anodic  $\text{Ni}^{\text{II/I}}$  couple. The resultant  $\text{Ni}^{\text{I}}$  species, which is assumed to be tetrahedral, is stable in air for extended periods.<sup>43</sup> The electrochemical generation and stabilization of  $\text{Ni}^{\text{I}}$  centres by 2,6-diiminopyridyl ligands (41) in  $[\text{Ni}(\text{41})_2]^{2+/+}$  has been reported.<sup>44</sup>

The mechanisms and kinetics of  $\text{CO}_2$  reduction by  $\text{Ni}^{\text{I}}$  macrocycles have been investigated.<sup>45</sup>

An electrochemical study of  $\text{Ni}^{\text{II}}$  meso-tetraphenyl-homoporphyrins, -secochlorins, and -chlorophin has shown that

the rigid homoporphyrin complexes are reduced at the ligand sites. In contrast, the more flexible chlorin and secochlorin complexes form  $\text{Ni}^{\text{I}}$  complexes upon reduction as the increased flexibility can better accommodate the larger  $\text{Ni}^{\text{I}}$  ion.<sup>46</sup>

### 4.3 P- and As-donor Complexes

A series of air-sensitive trigonal bipyramidal and trigonal pyramidal  $\text{Ni}^{\text{I}}$  complexes,  $[\text{Ni}(\text{PR}_3)_4]^+$ ,  $[\text{NiX}(\text{PR}_3)_3]$ ,  $[\text{NiX}(\text{AsR}_3)_3]$  ( $\text{X}$  = halide), and  $[\text{Ni}(\text{tripod})]^+$  and  $[\text{NiX}(\text{tripod})]$  (tripod = face-capping tripodal P, As ligand), have been reported.<sup>47</sup> The methods of synthesis of these species are varied, but essentially are based on the reduction of  $\text{Ni}^{\text{II}}$  or oxidation of  $\text{Ni}^0$  precursors. A range of four- and five-coordinate  $\text{Ni}^{\text{I}}$  complexes have been structurally characterized and some of these are illustrated in (42)–(46).

The magnetic moments of these complexes are consistent with the presence of one unpaired electron. Unusual three-coordinate  $\text{Ni}^{\text{I}}$  species (47) and (48) have been isolated using sterically hindered amido ligands.<sup>48</sup>

### 4.4 S-donor Complexes

The reductive electrochemistry of several  $\text{Ni}^{\text{II}}$  complexes of unsaturated dithiolate ligands has been examined.<sup>49</sup> On the basis of the electrochemical redox potentials, EPR spectral evidence, and SCF calculations, these reduction products are best formulated as  $\text{Ni}^{\text{I}}$  complexes for dithiocarbamate and 1,2-dithiolene ligands, and as  $\text{Ni}^{\text{II}}$  stabilized ligand-radical anions for dithiodiketonate species. It is often difficult to assign electron-density distributions within a molecule, particularly with delocalized ligands such as dithiolenes.

## 5 NICKEL(II)

The literature on the coordination chemistry of  $\text{Ni}^{\text{II}}$  is vast, and this brief review can only cover aspects of this chemistry. Essentially, all types of ligands that have been used for metal coordination chemistry have been investigated with  $\text{Ni}^{\text{II}}$ .

### 5.1 Cyanide Complexes

$[\text{Ni}(\text{CN})_2]$  is a polymeric material with the  $\text{CN}^-$  ligand bridging between  $\text{Ni}^{\text{II}}$  ions (49).  $[\text{Ni}(\text{CN})_4]^{2-}$  (50) is a particularly stable, yellow  $\text{Ni}^{\text{II}}$  species with a formation constant of some  $10^{30}$ . The complex is diamagnetic and square-planar at  $\text{Ni}^{\text{II}}$  with  $\text{Ni}-\text{C} = 1.86 \text{ \AA}$ .<sup>50</sup> The solid-state structure also shows stacking of these planar layers to give a  $\text{Ni}^{\text{II}}-\text{Ni}^{\text{II}}$  interaction with a  $3.30 \text{ \AA}$  separation. This type of stacking interaction is relatively common for square-planar  $\text{Ni}^{\text{II}}$  complexes. Addition of another  $\text{CN}^-$  ligand to  $[\text{Ni}(\text{CN})_4]^{2-}$  affords  $[\text{Ni}(\text{CN})_5]^{3-}$ , which shows square pyramidal (51) or trigonal bipyramidal (52) structures depending upon the counterion (equation 7,  $K_{\text{eq}} = 0.28$  at  $298 \text{ K}$ ).<sup>51</sup>

Recent work has indicated that  $\text{Ni}^{\text{II}}$  complexes can interact with buckminsterfullerene,  $\text{C}_{60}$ , and related fullerenes<sup>50</sup> (see **Carbon: Fullerenes** and Section 5.2).

## 5.2 N-donor Complexes

Ni<sup>II</sup> amine chemistry was investigated by Werner as part of his classic experiments on metal coordination chemistry.<sup>52</sup> This work led to an understanding of ligand field and the chelate effects, and pioneered the modern era of coordination, organometallic, and bioinorganic chemistry.<sup>53</sup> The chelate effect is illustrated by comparison of the stepwise stability constants for [Ni(NH<sub>3</sub>)<sub>6</sub>]<sup>2+</sup> (**53**) ( $\log K_1 - \log K_6 = 2.36, 1.90, 1.55, 1.23, 0.85, 0.42$ , respectively) and [Ni(en)<sub>3</sub>]<sup>2+</sup> (**54**) ( $\log K_1 - \log K_3 = 7.66, 6.40, 4.55$ , respectively), which shows greater stability for the latter bidentate five-membered chelate system. Further, replacement of en by pn leads to the formation of [Ni(pn)<sub>3</sub>]<sup>2+</sup> (**55**), which is less stable owing to the larger six-membered chelate ring. A wide variety of substituted amine complexes of the type [Ni(en)<sub>2</sub>X<sub>2</sub>]<sup>x+</sup> have been reported.

Polychelate triamine and tetraamine ligands can form even more stable complexes with Ni<sup>II</sup>. For example, 2,3,2-tet (**56**) forms a particularly stable, yellow, square-planar Ni<sup>II</sup> complex, [Ni(2,3,2-tet)]<sup>2+</sup> (**57**), which is some 10<sup>2</sup> times more stable than the corresponding [Ni(2,2,2-tet)]<sup>2+</sup> (**58**). This illustrates the variation of stability constant with ligand size. Interestingly, [Ni(2,2,2-tet)]<sup>2+</sup> can be regarded as somewhat strained owing to the presence of three, five-membered ring chelates within an equatorial plane. This strain can be released by formation of the *cis* octahedral

species [Ni(2,2,2-tet)(NCS)<sub>2</sub>] (**59**), which is formed readily on addition of <sup>-</sup>NCS to a solution of [Ni(2,2,2-tet)]<sup>2+</sup>.<sup>54</sup>

Many examples of Ni<sup>II</sup> complexes containing pyridyl, substituted pyridyl, imidazoles, pyrazoles, and related heterocyclic N-donor ligands have been reported, for example, [Ni(L)<sub>4</sub>X<sub>2</sub>] (X = halide, L = monodentate N-donor), [Ni(LL)<sub>3</sub>], [Ni(LL)<sub>2</sub>X<sub>2</sub>] (LL = chelate N-donor, for example, bipy, phen).<sup>55</sup> These compounds can be very readily prepared by reaction of NiX<sub>2</sub> and related Ni<sup>II</sup> starting materials with L and LL. The complexes [Ni(LL)<sub>3</sub>]<sup>2+</sup> (LL = bipy (**60**), phen) are normally isolated as racemic mixtures of (+) and (−) enantiomers, which can be resolved by crystallization with chiral counter anions.<sup>56</sup> Sterically hindered heterocyclic chelates or chelates with a small bite angle tend to form binuclear and polynuclear structures. For example, reaction of Ni<sup>II</sup> salts with 1,8-naphthyridine (**61**) affords an unusual species in which the tight chelate bite of the ligand leads to the formation of a Ni<sup>I</sup>–Ni<sup>II</sup>-bonded dimer [Ni<sub>2</sub>(**61**)<sub>4</sub>Br<sub>2</sub>]<sup>+</sup> (**62**). The Ni–Ni distance in (**62**) is 2.41 Å with Ni–N(av) = 2.11 Å.<sup>57</sup> Magnetic and EPR data on this complex suggest that it is a spin-delocalized system with an average oxidation state of +1.5 on each Ni. Second-sphere coordination of [Ni(H<sub>2</sub>O)<sub>5</sub>py]<sup>2+</sup> in a calixarene host has been reported.<sup>58</sup>

The tetradentate amine ligand (**63**) (**L**) displays an unusual binding to  $\text{Ni}^{\text{II}}$  ions to form the complex  $[\text{Ni}_2\text{L}_3]^{4+}$ . This species does not show the expected helical structure but incorporates two ligands each bound to a  $\text{Ni}^{\text{II}}$  ion in a tetradentate manner with the third ligand **L** in a bis-bidentate bridging mode.<sup>59</sup> Such a structure has been previously observed for the binding of siderophore alcaligin to  $\text{Fe}^{\text{III}}$ .

The structural trends and magnetic behavior of polynuclear  $\text{Ni}(\text{II})$  and  $\text{Mn}(\text{II})$  azido bridged complexes have been assessed.<sup>60</sup>

A very wide range of Schiff-base polychelate ligand complexes of  $\text{Ni}^{\text{II}}$  have been reported. These complexes can be prepared by reaction of  $\text{Ni}^{\text{II}}$  with the preformed ligand. More frequently, however, the complex is prepared in one step by Schiff-base condensation of the free aldehyde or ketone with the corresponding amine in the presence of  $\text{Ni}^{\text{II}}$ . The  $\text{Ni}^{\text{II}}$  ion thereby acts as a template, bringing together and stabilizing the intermediates and final product of the reaction.<sup>61</sup> Scheme 4 illustrates some of the ligands that have been prepared and complexed to  $\text{Ni}^{\text{II}}$ .

The report by Curtis<sup>62</sup> of the condensation of  $[\text{Ni}(\text{en})_3]^{2+}$  with acetone to give the open-chain condensation product and subsequently the macrocyclic complex (equation 8) was the first example of the synthesis of N-donor macrocycles by a metal template, and predates work on the oxycrown ligands such as 18-crown-6 ( $[\text{18}] \text{aneO}_6$ ).

An enormous, wide-ranging literature on  $\text{Ni}^{\text{II}}$  macrocyclic chemistry is now available (see Section 5.7). The H-bonded dimethylglyoxime complex  $[\text{Ni}(\text{dmgH})_2]$  (**64**) is one of the more important, since this species is used for the gravimetric determination of Ni. Like many square-planar  $\text{Ni}^{\text{II}}$  complexes it stacks in the solid state with a Ni–Ni separation of 3.24 Å.<sup>63</sup> Related  $\text{Ni}^{\text{II}}$  complexes of functionalized dmg ligands frequently show this type of stacking interactions.

There has been an explosion in interest in diimine  $\text{Ni}^{\text{II}}$  complexes such as (**65**) since the report of Brookhart and coworkers detailing<sup>64</sup> their activity in the polymerization of alkenes with toleration of functional groups such as ethers, esters, and carboxylic acids. The incorporation of steric bulk within the ligand framework, that is, alkyl groups on the aromatic rings, is crucial for efficient polymerization rather than oligomerization.<sup>64</sup>

$\text{Ni}^{\text{II}}$  octaethylporphyrin has been cocrystallized with  $\text{C}_{70}$ , in which the eight ethyl groups are arranged so that they encircle the  $\text{C}_{70}$ . This allows the close face–face contact of two flat  $\text{Ni}^{\text{II}}$  porphyrins.<sup>65</sup> This contrasts with the structure of  $\text{Ni}^{\text{II}}$  octakis(dimethylamino)porphyrazinato with  $\text{C}_{60}$  in which the porphyrazinato ligand is warped to a significant degree with each  $\text{C}_{60}$  lying in a cleft formed by two steeply inclined  $\text{Ni}^{\text{II}}$  porphyrazinates; there is additional  $\pi$ -stacking between the  $\text{C}_{60}$  molecules to produce a zig-zag chain. By contrast the analogous copper octakis(dimethylamino)porphyrazinato complex remains flat when cocrystallized with  $\text{C}_{60}$ .<sup>66</sup>

The tetraazamacrocyclic complex (**66**) adopts a saddle shape about  $\text{Ni}^{\text{II}}$  and allows the formation of a 1:1 supramolecular complex with  $\text{C}_{60}$  and a 2:1 complex with other

### Scheme 4

globular molecules for example, 1,2-dicarbododecaborane and the phosphorus chalcogenide  $P_4S_3$ .<sup>67</sup>

A range of complexes incorporating organic nitriles, nitrosyls, cyanates, thiocyanates, pyrazolyl borates, and azides have been reported.<sup>1,2</sup>

### 5.3 P-, As-, and Sb-donor Complexes

A very large number of phosphine, phosphite, stibine, and arsine complexes of type four-coordinate  $[NiX_2(ER_3)_2]$  and five-coordinate  $[NiX_2(ER_3)_3]$  ( $X$  = halide) have been reported, although this area is dominated by complexes of tertiary phosphines. The complexes  $[NiX_2(ER_3)_2]$  can be either tetrahedral (67) or square-planar (68), depending upon the electronic and steric effect of the coordinated phosphine, arsine, and stibine ligands (see Section 2).<sup>68</sup>

1,5,9-Triethyl-1,5-9-triphospacyclododecane reacts with  $NiBr_2$  to form an unusually distorted four-coordinate complex (69) as a result of constraints imposed by the macrocyclic ligand.<sup>69</sup> Indeed, the coordination geometry at Ni can best be described as a trigonal bipyramidal with a vacant vertex. Surprisingly, this apparent vacancy only leads to low activity in the polymerization of ethane.<sup>69</sup>

The square-planar complex (70) incorporating a  $C_2$  symmetric diphosphine catalyzes the polymerization of ethene,<sup>70</sup> which is somewhat surprising as diphosphine

complexes tend to be much less active than related diimine complexes (see Section 5.2).

The  $Ni^{II}$  complex incorporating mixed-donor P/O-ligands find industrial application in the Shell Higher Olefin Process (SHOP) to yield  $\alpha$ -alkenes, while the complex (71) has been shown to be active in the polymerization of olefins and will also tolerate functionalized monomers such as methyl methacrylate.<sup>71</sup> Grubbs and coworkers have adapted the standard SHOP catalyst to yield a highly active family of catalysts (e.g. 72) for the polymerization of low-branched polyethylene.<sup>72</sup> This is in contrast to the diimine catalysts (Section 5.2) which lead to a more highly branched polyethylene.

An extensive range of polychelate P-donor and mixed P/N-, P/S-, P/O-, and P/C-donor ligand complexes have been

Scheme 5

prepared.<sup>1,2</sup> Their complexation to  $\text{Ni}^{\text{II}}$  is based, in general, on four-coordinate  $\text{Ni}^{\text{II}}$  species in equilibrium, in the presence of other ligands, with five- and six-coordinate products. Some of the complexes that have been prepared are illustrated in Scheme 5.

#### 5.4 O-donor Complexes

$[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$  (**73**) is the main cation formed when  $\text{Ni}^{\text{II}}$  is dissolved in aqueous solution in the absence of other coordinating ligands; a second hydration sphere of some 15 water molecules has been proposed.<sup>73</sup> In addition, most simple salts written as  $\text{NiX}_2 \cdot x\text{H}_2\text{O}$  actually contain the hexaaqua ion  $[\text{Ni}(\text{H}_2\text{O})_6]^{2+}$ . Under alkaline conditions,  $\text{Ni}^{\text{II}}$ -hydroxy

species are formed, including  $[\text{Ni}(\text{OH})_6]^{4-}$ ,  $[\text{Ni}(\text{OH})_4]^{2-}$ , and  $[\text{Ni}_4(\text{OH})_4]^{4+}$  (**74**), which presumably has a cubane structure.<sup>74</sup>

Complexes such as  $[\text{Ni}(\text{ROH})_6]^{2+}$  and  $[\text{NiX}_2(\text{ROH})_4]$  can be generated under anhydrous conditions, although they tend to be water sensitive and can be readily hydrolyzed.<sup>75</sup> O-Donor ligands such as alcohols, ethers, and ketones are in general very poor donors to  $\text{Ni}^{\text{II}}$  and so their complexes are labile and often unstable. The structure of  $[\text{NiBr}(\text{EtOH})_4]^+$  (**75**) shows it to be a halo-bridged dimer.

Alkoxide complexes of stoichiometry  $[\text{Ni}(\text{OR})_2]$  can be prepared by reaction of simple  $\text{Ni}^{\text{II}}$  salts  $\text{NiX}_2$  with  $\text{RO}^-$ .<sup>73</sup> In general, the structures of these complexes are not known for certain, although the X-ray structure of  $[\text{Ni}_4(\text{OMe})_4(\text{acac})_4(\text{MeOH})_4]$  (**76**) confirms<sup>76</sup> it to be based on a  $\text{Ni}_4(\text{OMe})_4$  cube. Similar cubane structures have been proposed for a variety of other  $\text{Ni}^{\text{II}}$  alkoxide complexes.

Reaction of  $\text{Ni}^{\text{II}}$  with acac affords *trans*- $[\text{Ni}(\text{acac})_2(\text{H}_2\text{O})_2]$  (**77**), which can be dehydrated to  $[\text{Ni}(\text{acac})_2]$  (**78**).  $[\text{Ni}(\text{acac})_2]$  is actually trimeric with bridging acac ligands.<sup>77</sup> The complexes  $[\text{Ni}(\text{acac})_2(\text{L})_2]$  ( $\text{L} = \text{py}$  and related amine ligands) have been prepared, and some structurally characterized. Related tropolone, quinone, and catechol complexes have been reported.<sup>1,2</sup> Coupled electronic states in the complexes *trans*- $[\text{MCl}_2(\text{H}_2\text{O})_4]^{n+}$  complexes ( $\text{M} = \text{Ni}^{2+}, \text{Co}^{2+}, \text{V}^{3+}$  and

$\text{Cr}^{3+}$ ) have been probed by absorption and luminescence spectroscopy. The strongest interaction occurs for the  $\text{Ni}^{\text{II}}$  complex, where the lowest energy singlet state is very close in energy to a spin allowed crystal field band, giving rise to intense vibronic patterns.<sup>78</sup>

Treatment of  $\text{Ni}^{\text{II}}$  salts with acetic acid affords *trans*- $[\text{Ni}(\text{O}_2\text{CMe})_2(\text{H}_2\text{O})_4]$  (**79**) incorporating monodentate acetate ligands. By altering the reaction conditions and the carboxylic acid, complexes of type *trans* and *cis*  $[\text{Ni}(\text{O}_2\text{CR})_2(\text{L})_2]$  (**80**) ( $\text{L} = \text{N-}, \text{O-donor ligands}$ ) in which the carboxylate moiety is acting as a bidentate ligand can be prepared.<sup>79</sup> Binuclear species of the type  $[\text{Ni}_2(\text{O}_2\text{CR})_4(\text{L})_2]$  (**81**) can also be synthesized,<sup>80</sup> and a cubane complex  $[\text{Ni}_4(\text{OMe})_4(\text{O}_2\text{CMe})_2(\text{L})_4]^{2+}$  ( $\text{L} = \text{dinitrile ligand}$ ) (**82**) has been reported.<sup>81</sup>

$[\text{Ni}(\text{NO}_3)_2]$  is a common starting material for  $\text{Ni}^{\text{II}}$  coordination chemistry, since the nitrato ion is not a very strong donor. However, many nitrato<sup>82</sup> and nitrito<sup>83</sup> complexes are known in which these ligands are bound directly to

Scheme 6

Ni<sup>II</sup> either as monodentate, bidentate, or bridging ligands. Differentiation between these modes of coordination can be difficult in the absence of good X-ray structural data, although IR spectroscopy has been used effectively. The different bonding modes of NO<sub>3</sub><sup>-</sup> and NO<sub>2</sub><sup>-</sup> ligands are summarized in Scheme 6.

### 5.5 S-, Se-, and Te-donor Complexes

The chemistry of Ni<sup>II</sup> with S-ligands is not as well-developed as for N- and O-donor ligands. This is partly due to the formation of insoluble Ni<sup>II</sup> sulfide polymers. The ability of S<sup>2-</sup> to act as a bridging and capping ligand has led to the formation of polynuclear cluster species such as [Ni<sub>9</sub>(μ<sup>4</sup>-S)<sub>3</sub>(μ<sup>3</sup>-S)<sub>6</sub>(PEt<sub>3</sub>)<sub>6</sub>]<sup>2+</sup> (**83**),<sup>84</sup> [Ni<sub>3</sub>(μ<sup>3</sup>-S)<sub>2</sub>(PEt<sub>3</sub>)<sub>6</sub>]<sup>2+</sup> (**84**), and [Ni<sub>3</sub>(μ<sup>3</sup>-S)<sub>2</sub>(SH)(PEt<sub>3</sub>)<sub>5</sub>]<sup>2+</sup> (**85**).<sup>85</sup> Reaction of [Ni(OAc)<sub>2</sub>] with ammonium polysulfide affords [Ni(S<sub>4</sub>)<sub>2</sub>]<sup>2-</sup> (**86**) in good yield as a square-planar, diamagnetic product.<sup>86</sup>

A range of dithiocarboxylate, dithiocarbamate, xanthate, dithioformate, thioformate, and salsac complexes have been reported for Ni<sup>II</sup>.<sup>1,2</sup> These ligands are illustrated in Scheme 7. Many of the complexes are square-planar of type [Ni(L)<sub>2</sub>] with the mono negatively charged ligand chelating to the Ni<sup>II</sup> center, although there are examples where the complexes stack in the solid state. Dithiolene complexes of Ni<sup>II</sup> are of particular interest since they are generally redox active at the metal and/or ligand centers.

Work on Ni-thiolate complexes has focused on the synthesis of mononuclear, S-bridged polynuclear, cluster, and cubane model complexes of relevance to active site in biological systems (see Section 8).<sup>87,88</sup> Scheme 8 illustrates some of the thiolate complexes that have been prepared.

The synthesis of homoleptic Ni-thiolate complexes [Ni(L)<sub>4</sub>] (L = hindered thiolate) has been reported by Armstrong and coworkers.<sup>89</sup> Preparations of Ni<sup>II</sup> thiolates

complexes. By cyclic voltammetry, the Ni complexes display a reversible  $\text{Ni}^{\text{II}}\text{--Ni}^{\text{I}}$  reductions and irreversible ligand-based oxidation presumably to give unstable thiyl radical intermediates. The bis(sulfone) complexes, however, show reversible  $\text{Ni}^{\text{II}}\text{--Ni}^{\text{III}}$  oxidative processes as do the analogous complexes where the S-centres have been alkylated.<sup>91</sup> The possibility for a two centred Ni-SR site to function in an oxidative-addition mode was suggested as an intriguing solution developed by Nature to achieve the desired reactivity.

Holm and coworkers have investigated the structural and redox properties of mixed N/S-donor and related oxime  $\text{Ni}^{\text{II}}$  complexes, for example, (92) and (93), and have generated and studied the corresponding  $\text{Ni}^{\text{III}}$  species.<sup>92</sup>

Significantly,  $\text{Ni}^{\text{II}}$  dithiolenes have been shown to be effective for the electrochemical separation of alkenes from complex streams. No poisoning was observed with common impurities including hydrogen, carbon monoxide, acetylene, or hydrogen sulfide. Reactivity of these complexes occurs via

alkene binding to S-centres rather than at the Ni (Scheme 9) reflecting the radical nature of these ligands.<sup>93</sup>

## 5.6 Halide Complexes

Anhydrous  $\text{NiX}_2$  ( $\text{X} = \text{F}, \text{Cl}, \text{Br}, \text{I}$ ) can be prepared by reaction of elemental Ni with the free halide.<sup>94</sup> These

species are polymeric and show octahedral coordination at  $\text{Ni}^{\text{II}}$ . The trihalo complexes  $[\text{NiX}_3]^-$  also show octahedral coordination at  $\text{Ni}^{\text{II}}$  via bridging  $\mu^2\text{-Cl}_3$  units. The tetrahedral tetrahalo complexes  $[\text{NiX}_4]^{2-}$  are readily prepared by reaction of  $\text{NiX}_2$  with excess  $\text{X}^-$ . Substituted species  $[\text{NiX}_3(\text{L})]^-$  ( $\text{L} = \text{py}$ , substituted  $\text{py}$ ,  $\text{PPh}_3$ ) have been isolated as tetrahedral complexes.

### 5.7 Open-chain Mixed Donor and Macrocyclic Complexes

The redox noninnocence of the 2-mercapto-3,5-di-tert-butylaniline ligand has recently been investigated with  $\text{Ni}^{\text{II}}$  ions.<sup>95</sup> The spectroelectrochemistry of the complex displays a range of electron transfers where the monocation, the neutral species, and the mono- and dianions have been characterized. In a related manner, Wieghardt and coworkers have reported the first example of a stable N, O-coordinated *o*-iminobenzoquinone via air oxidation of the initial  $\text{Ni}^{\text{II}}$  complex with 2-anilino-4,6-di-tert-butylphenol (**94**).<sup>96</sup> The analogous *o*-iminobenzosemiquinonate  $\pi$ -radical complex was also isolated for this system and earlier for the bis-(*o*-iminobenzosemiquinonate)nickel(II) complex.<sup>97</sup>

In recent years, the development of new concepts for the rational design of larger, more complex molecules has led to considerable progress in supramolecular chemistry to afford structures of a variety of symmetries, sizes, and stoichiometries.  $\text{Ni}^{\text{II}}$  complexes have provided versatile molecular tectons in a plethora of such structures.

The aggregation of  $\text{Ni}^{\text{II}}$  complexes using amine-thiolate ligands such as (**95**) has been observed to yield homo-hexanuclear complexes. Fascinating pinwheel motifs have been observed where two Ni centres bridge four Ni amino-thiolate complexes.<sup>98</sup> Here, both the bite angle of the  $\text{S}^- - \text{Ni} - \text{S}^-$  unit and the choice of bridging metal ion influence whether a simple trinuclear aggregate is favoured or a higher motif.<sup>98</sup>

The imino-carboxylate ligand (**96**) coordinates to  $\text{Ni}^{\text{II}}$  in an equatorial manner to yield the monomer tecton  $[\text{Ni}(\text{L})(\text{MeOH})_2]$ . Subsequently, in the presence of templating lanthanide or group II metal ion these  $\text{Ni}^{\text{II}}$  complexes aggregate into an octahedral cage  $\{\text{M}[\text{Ni}(\text{L})]_6\}^{x+}$  ( $\text{M} = \text{Sr}^{\text{II}}$  or  $\text{Ba}^{\text{II}}$ ,  $x = 2$ ,  $\text{M} = \text{La}^{\text{III}}$ ,  $\text{Ce}^{\text{III}}$ ,  $\text{Pr}^{\text{III}}$  or  $\text{Nd}^{\text{III}}$ ,  $x = 3$ ).<sup>99</sup> However, in the presence of group I metal ions, aggregates of the alkaline metal-oxide cations template various cage compounds. For example,  $\text{Na}^+$  forms the trigonal bipyramidal  $[\text{Na}_5\text{O}]^{3+}$  core within a tricapped trigonal prismatic  $[\text{Ni}(\text{L})]_9$  aggregate to yield  $\{(\text{Na}_5\text{O}) \subset [\text{Ni}(\text{L})]_9(\text{MeOH})_3\}(\text{BF}_4)_2 \cdot \text{OH} \cdot \text{CH}_3\text{OH}$ , whilst  $\text{Li}^+$  forms a tetrahedral  $[\text{Li}_4\text{O}]^{2+}$  core within a hexanuclear open cage  $[\text{Ni}(\text{L})]_6$  in  $\{(\text{Li}_4\text{O}) \subset [\text{Ni}(\text{L})]_6(\text{MeOH})_3\}(\text{ClO}_4)_2 \cdot 1.85 \text{CH}_3\text{OH}$ .<sup>99</sup>

Complexes of  $\text{Ni}(\text{OAc})_2$  with 6-chloro-2-pyridonate (**97**) have been organized into an elegant  $\text{Ni}_{12}$  wheel, which has been investigated as a 'single-molecule magnet'.<sup>100,101</sup> With 3-methyl-3-pyrazol-5-one (**98**) the larger  $\text{Ni}_{24}$  wheel has been assembled.<sup>102</sup>

Bis(thiosemicarbazide)nickel(II) forms charge augmented double hydrogen-bonded chains with 1,4-terephthalate and trans-fumarate anions, which are further linked into sheets by hydrogen bonds between the  $\text{N}-\text{H} \cdots \text{O}$  units. The methylation of the primary amine disrupts these interactions markedly so that hydrogen-bonded sheets result, involving now molecules of water.<sup>103</sup>

Crystals of  $\text{Ni}(\text{NO}_3)_2$  with 4,4'-bipyridine produce a ladder type framework polymer, which can be desolvated to yield a stable porous solid.<sup>104</sup> The adsorption of methanol has then been studied and shown to cause a guest-driven solid-to-solid transformation. Fascinatingly, this material is able to accept

toluene into its pores, in spite of the pore window being lower than the cross-sectional area of toluene.<sup>105</sup> Molecular frameworks which grow as homochiral single crystals have been realized through the use of 1,3,5-benzenetricarboxylic acid, nickel(II) nitrate and 1,2-propanediol. The chiral 1,2-propanediol represents the first demonstration that chiral molecules can specifically template helix handedness in a chiral porous framework solid.<sup>106</sup>

Van Koten and coworkers have described the first example of a dendrimer employed as a catalyst support (Scheme 10).<sup>107</sup> This system is based upon diaminoarylnickel(II) complexes attached to the dendrimer surface and catalyze the Kharasch-type additions of polyhalogenoalkanes to alkenes. There is a clear advantage with regard to catalyst recovery, although in comparison to the analogous mononuclear catalyst the activity of the supported material was reduced.<sup>107</sup>

Supramolecular interactions have been exploited in the extraction of Ni<sup>II</sup> salts using ditopic ligands (e.g. **99**) with specific binding sites for both the cation, in the salen N<sub>2</sub>O<sub>2</sub><sup>2-</sup>, and the anion being hydrogen-bonded to the external protonated amines.<sup>108</sup> The formation of metallomacrocycles and the supramolecular chemistry of salen type complexes for cation binding studies with alkaline-earth metal ions has been investigated.<sup>109</sup>

A very extensive and wide-ranging literature has built up around the coordination chemistry of Ni<sup>II</sup> about N-donor Schiff-base ligands (see Section 5.2), open-chain mixed-donor ligands, and macrocyclic ligands. This burgeoning area is based on the ease of complexation of Ni<sup>II</sup> by these types

Scheme 10

of ligands. Interest in these types of complexes derives from their potential and practical uses in metal extraction processes, metal ion transport and recognition, for the stabilization of unusual oxidation state and stereochemistries at the metal center, as models for biological systems, in host-guest chemistry, and for small molecule binding and catalysis. Several reviews and texts specifically dealing with polydentate and macrocyclic complexes, porphyrins, and phthalocyanins have been published.<sup>110-112</sup> Scheme 11 illustrates some of the open-chain mixed-donor ligands and metal complexes that have been investigated.

Much of the macrocyclic chemistry of Ni<sup>II</sup> is based on Schiff-base template condensation reactions. The pioneering work of Curtis<sup>62</sup> showed that the condensation of en and acetone could be templated by Ni<sup>II</sup> to afford the corresponding tetraaza macrocycle (equation 9). Related template condensation reactions are illustrated in Scheme 12.

Subsequently, syntheses of tri-, tetra-, penta-, and hexaaza macrocycles, using methods developed by Richman and Atkins, have been published.<sup>113</sup> More recently, methods have been developed for the synthesis of polythioether macrocyclic ligands, some of which complex Ni<sup>II</sup> very strongly.<sup>114,115</sup> This is particularly significant since monodentate thioether ligands are notoriously poor ligands for Ni<sup>II</sup>.<sup>116</sup> Scheme 13 illustrates some of the macrocyclic ligands that have been coordinated to Ni<sup>II</sup> and some of the complexes derived from them (see also Scheme 3). Of particular interest has been the determination of conformations of the coordinated rings, the stereochemistry and configuration at the metal center, and the assignment of configuration at the coordinated N-donors, that is, whether the side groups are 'up' or 'down' relative to one another. The coordination geometry and electronic environment at Ni<sup>II</sup> can be specifically controlled by the protecting macrocyclic

Scheme 11

Scheme 12

### Scheme 13

ligand, and this has led to the stabilization of a range of  $\text{Ni}^{\text{I}}$  and  $\text{Ni}^{\text{III}}$  centers (see Sections 4 and 6, respectively).<sup>111,112</sup>

For example, an electrochemical investigation on  $[\text{Ni}[\text{18}] \text{aneN}_2\text{S}_4]^{2+}$  confirms a reversible  $\text{Ni}(\text{II})$ – $\text{Ni}(\text{III})$  couple and an irreversible reduction. In contrast,  $[\text{Ni}(\text{Me}_2[\text{18}] \text{aneN}_2\text{S}_4)]^{2+}$  shows an irreversible  $\text{Ni}(\text{II})$ – $\text{Ni}(\text{III})$  couple but a reversible  $\text{Ni}(\text{II})$ – $\text{Ni}(\text{I})$  process. This contrasting redox behavior can be rationalized by the different binding characteristics of the ligands (**100**).<sup>117</sup>

The binuclear nickel-thiolate macrocyclic complex (**101**) displays noteworthy redox behavior, in which one-electron oxidation yields a  $\text{Ni}^{\text{III}}$ .  $\text{Ni}^{\text{II}}$  product with significant delocalization of the unpaired electron density onto the bridging thiolate ligands and not onto the second nickel ion.<sup>118</sup> The charge delocalization consequently lies between the two redox extremes of nickel(III)-thiolate and nickel(II)-thiyl radical, thus mimicking the Ni–C state in  $[\text{NiFe}]$ hydrogenase (see Section 8).

$\text{Ni}^{\text{II}}$  macrocyclic complexes have also been investigated as covalent attachments to photosensitizers such as  $[\text{Ru}(\text{bipy})_3]^{2+}$ ,<sup>119</sup> and as interchelating agents for the cleavage of DNA.<sup>120</sup>

## 6 NICKEL(III)

The coordination chemistry of  $\text{Ni}^{\text{III}}$  has been reviewed,<sup>14</sup> and electron-transfer reactions of  $\text{Ni}^{\text{III}}$  and  $\text{Ni}^{\text{IV}}$  complexes

assessed.<sup>121</sup>  $\text{Ni}^{\text{III}}$  species are stabilized by  $\sigma$ -donor ligands and are excellent oxidizing agents. The complexes usually show tetragonally distorted octahedral geometries consistent with a  $d^7$  electron configuration; the EPR spectra of  $\text{Ni}^{\text{III}}$  species show  $g_{\perp} > g_{\parallel} \sim 2.0023$  assigned to a  $d_{z^2}^1$  ground-state configuration for an axially elongated octahedron. Coordination of solvent molecules such as MeCN to apical sites leads to hyperfine coupling to N in the  $g_{\parallel}$  component of the EPR spectrum.<sup>122</sup> Many  $\text{Ni}^{\text{III}}$  species have relatively short half-lives for decomposition and may be regarded as transient species.

The oxidation of a range of  $\text{Ni}^{\text{II}}$  complexes of open-chain mixed-donor ligands (Scheme 14) has generated  $\text{Ni}^{\text{III}}$  complexes that have been characterized by EPR spectroscopy.<sup>123</sup> Many of these complexes incorporate deprotonated amide and amino acid functionalities. The stabilization of  $\text{Ni}^{\text{III}}$  by diimino ligands has also been reported.<sup>44,92</sup>

A wide range of  $\text{Ni}^{\text{III}}$  complexes of aza macrocyclic<sup>124</sup> and porphyrin<sup>125</sup> ligands has been reported. The structures of  $[\text{Ni}[\text{9}] \text{aneN}_3]_2^{3+}$  (**102**), the thioether analogue  $[\text{Ni}[\text{9}] \text{aneS}_3]_2^{3+}$  (**103**),  $[\text{Ni}[\text{14}] \text{aneN}_4\text{Cl}_2]^+$  (**104**),  $[\text{Ni}(\text{R}_3[\text{9}] \text{aneN}_3)]$  ( $\text{R} = \text{CH}_2\text{CO}_2^-$ ) (**105**), and the  $\text{Ni}^{\text{III}}$  analogue of (**92**) confirm the stereochemical preference of  $\text{Ni}^{\text{III}}$  for distorted octahedral coordination.<sup>92,126</sup> The oxidation of organic substrates and biological materials by  $\text{Ni}^{\text{III}}$  macrocyclic species (generated by oxidation of  $\text{Ni}^{\text{II}}$  precursors) has been reported.<sup>127</sup> The generation of  $\text{Ni}^{\text{III}}$  species by pulse radiolysis has been a particularly useful technique for the study of kinetics and mechanism,<sup>128</sup> while the oxidative addition of  $\text{R}-\text{X}$  to  $\text{Ni}^{\text{I}}$  to form  $\text{Ni}^{\text{III}}$  species has been described (equation 10).<sup>129</sup>

Scheme 14

The ability of tetraazamacrocycles (**106**) to stabilize nickel ions in the +3 oxidation state has been employed to demonstrate redox switching of fluorescence. The wavelength of the emitted light is controlled through the choice of pendant group X.<sup>130</sup>

A limited series of phosphine and thiolene complexes of Ni<sup>III</sup> have been generated. These include the species [NiX<sub>3</sub>(PR<sub>3</sub>)<sub>2</sub>] and [M(L)<sub>2</sub>]<sup>−</sup> (L = dithiolene), although in the latter complexes the formation of Ni<sup>III</sup>-stabilized ligand-radical cations has been observed. The synthesis of [NiF<sub>6</sub>]<sup>3−</sup> has been reported.

## 7 NICKEL(IV)

Ni<sup>IV</sup> complexes are relatively rare and very few have been characterized fully. The structure of [NiF<sub>6</sub>]<sup>2−</sup> shows octahedral coordination with Ni–F = 1.72, 1.76 Å.<sup>131</sup> With Ni<sup>III</sup> and Ni<sup>IV</sup> centers deprotonation of coordinated amine occurs very readily, reflecting the requirement of these metal ions for electronegative ligands. Ni<sup>IV</sup> has been stabilized by polydentate oxime, amide, and amino acid ligands (see Scheme 14). Examples of Ni<sup>IV</sup> stabilized by dithiocarbamate and dithiolene ligands are now believed to be ligand-oxidized complexes. The stabilization of Ni<sup>IV</sup> in molybdates and niobates is also known. A highly unusual Ni<sup>IV</sup> cubane complex [Ni<sub>4</sub>Se<sub>4</sub>(Se<sub>3</sub>)<sub>5</sub>(Se<sub>4</sub>)]<sup>4−</sup> (**107**) has been isolated and characterized.<sup>132</sup>

## 8 BIOLOGICAL CHEMISTRY

A major impetus for the study of Ni redox chemistry has been provided by the discovery of paramagnetic Ni centers

in several biological systems.<sup>133,134</sup> Several enzymes are now known to contain Ni and in a number of these the Ni is thought to take part in redox reactions.<sup>135,136</sup>

Urease catalyzes the hydrolysis of urea to  $\text{NH}_3$  and  $\text{CO}_2$  and incorporates  $\text{Ni}^{\text{II}}$  in an octahedral environment.<sup>137</sup> The function of the Ni center(s) in these enzymes is thought to be analogous to that of  $\text{Zn}^{\text{II}}$  in carbonic anhydrase, to activate the urea substrate electrostatically to nucleophilic attack.<sup>138</sup> The binuclear  $\text{Ni}^{\text{II}}$  complex (**108**) displays urease activity, firstly via conversion of urea to ammonia and cyanate, followed by a second step involving the hydrolysis of the cyanate.<sup>139,140</sup> In addition, a related asymmetric complex reacts with urea and allows the structural characterization of the isocyanate product.

Methyl-coenzyme M reductase requires a Ni-containing prosthetic group for activity, Factor  $\text{F}_{430}$ . This is a Ni complex of a tetrahydroporphyrin which forms an octahedral Ni complex in the intact protein. The active ('reduced') form of this enzyme is EPR active ( $g_{\perp} = 2.23$ ,  $g_{\parallel} = 2.17$ ),<sup>141</sup> which is consistent with the formation of a  $d^9 \text{Ni}^{\text{I}}$  center. A recent X-ray structure of methyl-coenzyme M reductase shows the octahedral  $\text{Ni}^{\text{II}}$  ion bound in a tetrapyrrole hydrocorphin ring and the oxygen from a glutamine residue at the 5<sup>th</sup> site. The sixth site is occupied by either a thiol group of coenzyme M in the methyl-coenzyme M reductase<sub>oxl-silent</sub> structure or a sulfonate oxygen of coenzyme M in the methyl-coenzyme M reductase<sub>silent</sub> structure.<sup>142,143</sup>

Carbon monoxide dehydrogenase is a bacterial enzyme that catalyzes the interconversion of CO and  $\text{CO}_2$ , the active site has been shown to contain an asymmetric  $[\text{Ni}-4\text{Fe}-5\text{S}]$  cluster.<sup>144,145</sup> There have been two recent independent reports of X-ray structures for the bifunctional enzyme carbon monoxide dehydrogenase/acetyl-coenzyme A synthase. In both structures  $\text{Ni}^{\text{II}}$  is present bound within a  $\text{N}_2\text{S}_2$  polychelate, which via the thiolate donors bridges to either a Cu, Zn, or Ni ion, which in turn is bound to a  $4\text{Fe}4\text{S}$  cluster.<sup>146,147</sup> Helix-loop-helix peptides have been designed as scaffolds for the stabilization of  $\text{Ni}^{\text{II}}-\text{Fe}_4\text{S}_4$  bridged assemblies to model the active site of the A-cluster of carbon monoxide dehydrogenase. Herein, the  $\text{Fe}_4\text{S}_4$  is incorporated in the flexible loop of the

peptide and is bridged by a cysteine residue to the bound  $\text{Ni}^{\text{II}}$ ; this  $\text{Ni}^{\text{II}}$  appears to be in equilibrium with a peptide free  $\text{Ni}^{\text{II}}$  species.<sup>15,148</sup> Low molecular weight models for the active site of acetyl-coenzyme A synthase have been prepared (**109**,<sup>149</sup> **110**,<sup>150</sup> **111**,<sup>151</sup>), and these are also able to form higher aggregates containing more metal ions in the centre of the complexes.

Hydrogenase enzyme catalytically interconvert  $\text{H}_2$  and  $2\text{H}^+$ . The X-ray structure of  $[\text{NiFe}]$  hydrogenase has been solved for *Desulfovibrio gigas* to a resolution of 2.85 and 2.54 Å.<sup>152,153</sup> The active site comprises a heterobimetallic  $[\text{NiFe}]$  center, with the Ni ligated by four cysteines, two of which are terminal and two which bridge to iron (**112**). The Fe is ligated further by three nonprotein diatomics, namely, two cyanide and one carbonyl, a third bridging group completes the octahedral coordination sphere and is assigned as an oxo-oxygen more closely associated with the Ni than the Fe. Activation of the enzyme is believed to involve loss of the oxo-ligand and contraction of the nickel-iron separation to some 2.5–2.6 Å.<sup>154</sup>

The precise mechanistic detail of the enzymic reaction is not fully understood, although a  $\text{Ni}^{\text{III}}-(\text{H}_2)$  complex appears to be involved.<sup>155,156</sup> Crabtree and coworkers have published evidence for the first example of a  $\text{Ni}^{\text{II}}$  complex that interacts directly with  $\text{H}_2$ ,<sup>157</sup> while Lubitz and coworkers have proposed using multi-frequency EPR analysis a reaction scheme for  $\text{H}_2$  and  $\text{H}^+$  interconversion at the biosite (see Scheme 15).<sup>158</sup>

The active site of [NiFe] hydrogenase

Scheme 15

The synthesis and study of low molecular weight model complexes that mimic the electronic structure and coordination chemistry of the hydrogenase active site is a timely area of research and has been reviewed.<sup>159</sup> Typical examples of mixed Ni-Fe complexes that have been prepared include complexes (113),<sup>160</sup> (114),<sup>159</sup> (115),<sup>159</sup> and (116).<sup>161</sup>

## Abbreviations

H<sub>2ase</sub> = hydrogenase; Hbsms = 4-mercapto-3,3-methyl-1-phenyl-2-thiabutane; S<sub>cys</sub> = cysteine thiolate; psnet = bis(5-(diphenylphosphino)-3-thiapentanylamine; bdptz = 1,4-bis(2,2'-dipyridylmethyl)phthalazine; OTs = *p*-toluenesulfonate; tmen = *N,N,N',N'*-tetramethylethylenediamine; AA = acetohydroxamate anion; [PhTt<sup>*tert*</sup>Bu] = phenyltris(*tert*-butylthio)-methylborate; bipy = bipyridine.

## 1 INTRODUCTION

Recently, major progress has been made in solving the active-site structures of the nickel-containing metalloenzymes by single-crystal X-ray diffraction (the unsolved problem of bioinorganic chemistry as it exists in the 1980s–1990s) and in deducing the ways that nature activates/catalyzes reversible hydrogen oxidation (hydrogenases), hydrolysis of urea to ammonia and carbamate (ureases), reversible CO oxidation (carbon monoxide dehydrogenases), acetyl coenzyme assembly (acetyl coenzyme A synthase), and the formation of methane by the methanogens (methyl coenzyme M reductase). The high-resolution X-ray crystal structures of the active sites of the nickel-containing hydrogenases, carbon monoxide dehydrogenases (CODH/ACS), ureases, methyl coenzyme M reductase (MCR), as well as the role(s) of nickel in these enzymes have now been explored in detail. In such pursuit, extensive spectroscopic experiments and kinetic measurements on these enzymes have also been performed, as a

background for the subsequent modeling studies. Since the mechanism(s) of catalytic reactions by the microorganisms remain elusive at the present time, modeling approaches have been adopted to correlate the spectral and reactivity parameters of model compounds with those of Ni-containing enzymes and to derive conclusions regarding mechanistic and functional characteristics of the biological nickel site.

## 2 HYDROGENASE

### 2.1 Background

Hydrogen metabolism (reversibly catalyzed oxidation of H<sub>2</sub> molecules) in the biological energy cycle is mostly mediated by two types of metal-containing enzymes, [NiFe] hydrogenases, and [Fe] hydrogenases.<sup>1–5</sup> [NiFe] hydrogenase containing a [Ni–Fe] center that is believed to be the catalytic site for hydrogen activation functions more effectively in the direction of H<sub>2</sub> oxidation. The recent X-ray crystallographic studies of the active-site structure of [NiFe] hydrogenases isolated from *Desulfovibrio gigas*, *Desulfovibrio vulgaris*, *Desulfovibrio fructosovorans*, and *Desulfovibrio desulfuricans* ATCC27774 in combination with infrared spectroscopy have revealed an active site comprised of a heterobimetallic (S<sub>cys</sub>)<sub>2</sub>Ni(μ-S<sub>cys</sub>)<sub>2</sub>(μ-X)Fe(CO)(CN)<sub>2</sub> (X = O, OH) cluster (Figure 1). The bridging ligand X was proposed to be an oxide or hydroxide in the oxidized state, and was found to be absent in the reduced state. Three nonprotein diatomic groups (two cyanide and one carbonyl ligands) ligate the iron center.<sup>4–21</sup>

The nickel site has been proposed to be redox active and changes between Ni(III) and Ni(II), while the iron site remains as Fe(II) in all spectrally defined redox states of the enzyme.<sup>11–21,25–41</sup> The EXAFS/EPR studies indicate that the formal oxidation state of the Ni center is paramagnetic Ni(III) in Ni–A, Ni–B and Ni–C states.<sup>28–41</sup> Actually, the active form Ni–C (the paramagnetic Ni–C intermediate) of [NiFe] H<sub>2ase</sub> was proposed to exist as the [(S<sub>cys</sub>-H)Ni<sup>III</sup>-H-Fe] intermediates after an active state Ni–S1a (silent-active [(S<sub>cys</sub>-H)Ni<sup>II</sup>(S<sub>cys</sub>)<sub>3</sub>]) is passed. Ni–C is believed to be an intermediate in the catalytic cycle. Upon illumination,

**Figure 1** (a) A schematic drawing of the active site of [NiFe] hydrogenases as deduced from the crystallographic studies.<sup>6–10</sup> (b) A schematic drawing of the H-cluster of the CO-inhibited form of the *Clostridium pasteurianum* [Fe] hydrogenases as deduced from the recent X-ray crystallographic studies<sup>22–24</sup>

**Scheme 1** The possible redox states of the active center of [NiFe] hydrogenases.<sup>11–21,25–43</sup>

the Ni–C state is transformed into a fourth paramagnetic Ni–L state. These conversions are considered to correspond to photodissociation of proton species from the [Ni–Fe] center.<sup>28–41</sup> Interestingly, the recent X-ray crystal structures of CO-inhibited forms and single-crystal EPR studies of the reduced active site of [NiFe] H<sub>2</sub>ase isolated from *D. vulgaris* Miyazaki F implicate that the Ni–C intermediate is a formal Ni(III) oxidation state with a hydride (H<sup>−</sup>) bridging between the Ni and the Fe atoms and the sulfur atom of Cys 546 hydrogenated for the catalytic reaction of the enzyme.<sup>40,41</sup> In addition, the active form Ni–C has also been shown to contain a solvent exchangeable proton, assigned as an in-plane hydride, as a S–H proton directly interacting with nickel, or as H<sub>2</sub> from ENDOR studies.<sup>42,43</sup> Interpretations of these results tend to favor the assignment of a Cys–SH proton directly interacting with nickel. The redox states of the active center of [NiFe] hydrogenases are shown in Scheme 1.

The recent report of high-quality X-ray crystal structures of [Fe]-only hydrogenases isolated from *D. desulfuricans* (DdH<sub>2</sub>ase)/*Clostridium pasteurianum* (CpH<sub>2</sub>ase) revealed that the active sites are composed of a conventional [4Fe–4S] subcluster linked by a bridging cysteine to a dinuclear iron subcluster.<sup>22–24,44,45</sup> The crystal structures, in combination with FTIR data, suggest that the dinuclear iron subcluster is ligated by terminal CO and CN<sup>−</sup> diatomic molecules with the two iron atoms linked by a di(thiomethyl)-amine ligand (DdHase)/two thiolate ligands (CpHase) and a carbonyl group. Upon reduction, FTIR spectra and crystal structure show that the previously bridging CO shifts toward the distal iron that most likely serves as the primary hydrogen binding site.<sup>22–24,44,45</sup> Mössbauer studies of the H-cluster in [Fe] hydrogenases isolated from *C. pasteurianum* (CpH) showed that the dinuclear Fe subcluster contains a low-spin Fe<sup>II</sup>–Fe<sup>II</sup> site in the reduced state (H<sub>red</sub>), while it is in the mixed-valence Fe<sup>III</sup>–Fe<sup>II</sup> form in the oxidized state (H<sub>ox</sub> and H<sub>ox</sub>–CO).<sup>46</sup> It is generally believed that the dinuclear Fe subcluster of DdH<sub>2</sub>ase and CpH<sub>2</sub>ase may be assigned as [Fe<sup>II</sup>Fe<sup>II</sup>], [Fe<sup>I</sup>Fe<sup>II</sup>], and

[Fe<sup>I</sup>Fe<sup>I</sup>] in the fully oxidized (inactive), the oxidized (active), and reduced states, respectively.<sup>45,47–51</sup>

## 2.2 Structural Models

Designing and synthesizing structural model complexes, in addition to serving as spectroscopic references, may provide an essential understanding about the active-site construction and function of [Fe] and [NiFe] hydrogenases, and the role/function of CO, CN<sup>−</sup> ligands, and may elucidate the electronic structure of active centers of the binuclear subcluster.<sup>52–54</sup> Examples of structurally characterized, thiolate-bridged heterobimetallic NiFe complexes with iron coordinated by CO/NO ligands are few. [Ni{Fe(NS<sub>3</sub>)(CO)–S,S'}<sub>2</sub>] (NS<sub>3</sub>=[N(CH<sub>2</sub>CH<sub>2</sub>S)<sub>3</sub>]<sup>3−</sup>) (**1**) is made up of two trigonal bipyramidal Fe(NS<sub>3</sub>)(CO) units bridging to a central Ni(II) atom.<sup>55</sup> A review of the heterobimetallic NiFe compounds finds Ni–Fe distances ranging from 2.80 to 3.323 Å (Ni–Fe distance: **2**, 3.323(1) Å; **3**, 3.308(2) Å; **4**, 3.10 Å; **5**, 2.80 Å; **6**, 2.80 Å), far beyond the enzyme Ni–Fe distance. [(C<sub>6</sub>H<sub>4</sub>S<sub>2</sub>)Ni(μ-‘S<sub>3</sub>’)Fe(CO)(PMe<sub>3</sub>)<sub>2</sub>](‘S<sub>3</sub>’=bis(2-mercaptophenyl)sulfide (2−)) (**2**) nearly duplicates the donor atom set of [NiFe] hydrogenases centers with the ν(CO) frequency 1948 cm<sup>−1</sup> (KBr) corresponding to the most reduced Ni–R state of hydrogenases.<sup>56</sup> The Ni of [Fe(CO)<sub>2</sub>{N(CH<sub>2</sub>CH<sub>2</sub>S)<sub>3</sub>–S,S'}NiCl(dppe)] (**3**) is five-coordinate in a square pyramidal pattern and is displaced 0.307(2) Å from the base plane towards the chloride ligand in the apical site.<sup>57</sup> The unique NiFe heterotrimetallic (**4**) is formed by two {NiN<sub>2</sub>S<sub>2</sub>} fragments serving as a bidentate metathiolate ligand bound to {Fe(CO)<sub>2</sub>} motif.<sup>58</sup> Formation of [Ni<sup>II</sup>(N<sub>2</sub>S<sub>2</sub>)Fe(NO)<sub>2</sub>] (**5**) and [(NO)Ni<sup>0</sup>(S<sub>3</sub>)Fe(NO)<sub>2</sub>] (**6**) may be rationalized according to the ability of the chalcogenolate (or metal-modified chalcogenolate) ligand to stabilize the oxidized, {Fe(NO)<sub>2</sub>}<sup>9</sup>, or reduced, {Fe(NO)<sub>2</sub>}<sup>10</sup> forms.<sup>59,60</sup> The Ni<sup>II</sup>-bound dichalcogenolate stabilizes the electron-rich or reduced form and the [Ni<sup>0</sup>NO<sup>+</sup>] unit effectively generates a monoanionic dithiolate ligand donor set that stabilizes the oxidized form.

Mononuclear nickel-thiolate complexes may serve as precursors for synthetic goals of preparing Ni-Fe heterometallics in biological-type ligation settings. Structural models as  $[\text{Ni}(\text{CO})(\text{SPh})_n(\text{SePh})_{3-n}]^-$  ( $n = 0, 1, 2$ ) (7), a distorted square-planar  $\text{Ni}^{\text{II}}\text{-CO}$  complex, may be appreciated as possibilities for intermediates in biological reaction pathways or as structures important to CO-inhibitory processes in the [NiFe] enzyme.<sup>61,62</sup> Interestingly, the mononuclear  $\text{Ni}^{\text{III}}$   $[\text{Ni}(\text{SePh})(\text{P}(o\text{-C}_6\text{H}_4\text{S})_3)]^-$  complex (8) with S-donor ligands has been structurally characterized recently.<sup>63</sup> Complex (8) is five-coordinate with three equatorial S-donors, one axial selenolate Se-donor and one axial P-donor. The distorted square-planar  $[\text{Ni}(\text{SePh})(\text{P}(o\text{-C}_6\text{H}_4\text{S})_2(o\text{-C}_6\text{H}_4\text{SH}))]^-$  (9) with the thiol proton interacting with both the nickel and sulfur sites was verified in the solid state by the observation of one  $\nu_{\text{S-H}}$  stretching band ( $2274\text{ cm}^{-1}$ ) in its IR spectrum and subsequently confirmed by an X-ray diffraction study.<sup>63</sup> The H/D exchange

reaction between complex (9) and  $\text{D}_2\text{O}$  occurred in  $\text{CH}_3\text{CN}$  as indicated by IR and  $^2\text{H}$  NMR. The facile conversion of complex (9) into complex (8) accompanied by by-product  $\text{H}_2\text{O}$  was observed upon exposure of complex (9) to  $\text{O}_2$ . In  $[\text{Ni}(\text{bsms})_2]$  (10), a promising complex for new structural models of [NiFe] hydrogenases, the two ligands are coordinated with the thiolates in trans positions to each other.<sup>64</sup>  $[\text{Ni}_2(\text{L})]^{3+}$ , the one-electron oxidation product of  $[\text{Ni}_2(\text{L})]^{2+}$  (11), can be described with a proportion (ca. 30%) of the unpaired electron density delocalized onto the bridging thiolate ligands, that is, the charge delocalization lies between the  $[\text{Ni}^{\text{III}}(-\text{SR})]$  and  $[\text{Ni}^{\text{II}}(\cdot\cdot\text{SR})]$  redox extremes.<sup>65</sup>

### 2.3 Models of Hydrogenase Catalysis

Hydrogenases catalyze the heterolytic cleavage of the hydrogen molecule. During catalysis, the Ni ion in [NiFe] hydrogenase has been proposed to serve as the catalytic site, heterolytically splitting the  $\text{H}_2$  molecule into hydride and proton with the thiolate of  $\text{Cys}_{530}$  serving as a base. In model compounds, an electrochemical study provided evidence for such a  $\text{Ni}(\text{III})\text{-H}$  species generated by one-electron reduction of a nickel(II) macrocyclic complex accompanied by protonation.<sup>66</sup> Recently, two elegant examples have been provided,  $[\text{Ni}(\text{diphosphine})_2]^{2+}$  containing ligand-appended nitrogen bases (12) and  $[\text{Ni}(\text{NHPnPr}_3)(\text{'S}_3)]$  ( $\text{'S}_3^{2-}$  = bis(2-sulfanylnylphenyl)sulfide(2-)) (13).

In one interesting model compound, complex  $[\text{Ni}(\text{PNP})_2]^{2+}$  (PNP =  $\text{Et}_2\text{PCH}_2\text{NMeCH}_2\text{PEt}_2$ ) (12) is an electrocatalyst for the oxidation of hydrogen to protons, and stoichiometric reaction with hydrogen forms  $[\text{HNi}(\text{PNP})(\text{PNHP})][(\text{BF}_4)_2]$  in which the hydride ligand is associated with nickel and the proton is bound by nitrogen.<sup>67,68</sup> Complex  $[\text{HNi}(\text{PNP})(\text{PNHP})]^{2+}$  undergoes reversible deprotonation to yield  $[\text{HNi}(\text{PNP})_2]^+$ . Meanwhile, the hydride ligand and the NH proton of  $[\text{HNi}(\text{PNP})(\text{PNHP})]^{2+}$  undergo rapid intramolecular exchange with each other and intermolecular exchange with protons in solution. The proposed electrocatalytic reaction sequences are summarized in Scheme 2.<sup>67,68</sup> The one-electron oxidation of  $[\text{HNi}^{\text{II}}(\text{PNP})_2]^+$

**Scheme 2** A proposed mechanism for the oxidation of hydrogen. (Reprinted from *Inorg. Chem.*, 2003, **42**, 216–227. © 2003 American Chemical Society)

to  $[\text{HNi}^{\text{III}}(\text{PNP})_2]^{2+}$  is followed by rapid transfer of the proton bound to Ni in  $[\text{HNi}^{\text{III}}(\text{PNP})_2]^{2+}$  to the N atom of the chelating PNP ligand. A proton transfer occurs from the diphosphine ligand to give  $[\text{Ni}^{\text{I}}(\text{PNP})_2]^+$  and  $\text{HNEt}_3^+$  in the presence of triethylamine. Oxidation of  $[\text{Ni}^{\text{I}}(\text{PNP})_2]^+$  to  $[\text{Ni}^{\text{II}}(\text{PNP})_2]^{2+}$  completes the two-electron oxidation process.

Model compound  $[\text{Ni}(\text{NHPnPr}_3)(\text{'S}_3\text{'})]$  (**13**) was presumed to catalyze the heterolytic cleavage of  $\text{H}_2$  (reaction of  $\text{H}_2$  and  $\text{D}_2\text{O}$  yielding HD and HDO). Reactions of  $[\text{Ni}(\text{NHPnPr}_3)(\text{'S}_3\text{'})]$  with  $\text{D}_2$  and  $\text{D}_2\text{O}$  yielding  $[\text{Ni}(\text{NDPnPr}_3)(\text{'S}_3\text{'})]/\text{HD}$ , and  $[\text{Ni}(\text{NDPnPr}_3)(\text{'S}_3\text{'})]/\text{HDO}$ , individually, demonstrate that complex (**13**) is able to exchange NH protons with molecular  $\text{D}_2$  and with  $\text{H}^+$  or  $\text{D}^+$ .<sup>69</sup> The proposed mechanism of the catalyzed  $\text{D}_2/\text{H}^+$  exchange is shown in Scheme 3.<sup>69</sup>

Recent kinetics studies on protonation of  $[\text{Ni}(\text{SEt})(\text{Ph}_2\text{PCH}_2\text{CH}_2)_2\text{PPh}]^+$  (**14**) proposed that the proton interacts with both the nickel and sulfur sites,<sup>70</sup> consistent with the proposal of intramolecular proton transfer between cysteinyl sulfur and Ni atom in the Ni-based hydrogenases. Additionally, the mononuclear complex  $[\text{Ni}(\text{psnet})]^+$  (**15**) of known structure and a mildly negative redox potential can stoichiometrically evolve  $\text{H}_2$  from protic sources. On the basis of kinetics analysis, the reaction paths considered most probable involve steps of protic oxidative addition to Ni(I) to generate  $\text{Ni}^{\text{III}}\text{-H}^-$ , and electron transfer to Ni(III) followed

**Scheme 3** A proposed mechanism for the oxidation of hydrogen. (Reprinted from *Angew. Chem. Int. Ed. Engl.*, 2000, **39**, 561–563. © 2000 John Wiley & Sons, Ltd)

by protonation of bound hydride or the bimolecular reaction  $2\text{Ni}^{\text{III}}\text{-H}^- \rightarrow 2\text{Ni}^{\text{II}} + \text{H}_2$  to yield  $\text{H}_2$ .<sup>71</sup>

## 2.4 Models for the Iron Site of [NiFe] Hydrogenase

Examples of cyanide ( $\text{CN}^-$ ) coordination to iron(II) and the spectroscopic signals of dicyanide iron(II) thiolate carbonyl complexes ( $[(\text{CN})_2(\text{CO})\text{Fe}^{\text{II}}(\text{SR})_2]^{n-}$ ) are of much interest, particularly in catalytically active-site construction of the  $(\text{CysS})_2\text{Ni}(\mu\text{-Scys})_2\text{Fe}(\text{CN})_2(\text{CO})$  active site of [NiFe] hydrogenases. In the iron-site architecture of the [NiFe] hydrogenase active site, a vacant coordination site around iron, trans to the carbonyl ligand, may serve as a potential  $\text{H}_2$ -binding site and presumably plays an important role in biological hydrogen activation. By application of oxidative addition and stepwise ligand exchange route, *trans*, *cis*- $[(\text{CN})_2(\text{CO})_2\text{Fe}(\text{S}, \text{S-C-R})]^-$  ( $\text{R} = \text{OEt}$  **16**,  $\text{R} = \text{N}(\text{Et})_2$  **17**) were isolated and characterized by X-ray crystallography and infrared spectroscopy.<sup>72</sup> Photolysis of THF solutions of complexes (**16/17**) led to the formation of coordinatively unsaturated iron(II) dicyanocarbonyl thiolate complexes  $[(\text{CN})_2(\text{CO})\text{Fe}(\text{S}, \text{S-C-R})]^-$  ( $\text{R} = \text{OEt}$  **18**,  $\text{R} = \text{N}(\text{Et})_2$  **19**, respectively), with two cyanides occupying *cis* positions and a vacant site preferably *trans* to the CO ligand. Complexes (**18/19**) and Ni-A/Ni-C states of [NiFe] hydrogenases from *D. gigas* exhibit a similar one-band pattern in the  $\nu_{\text{CO}}$  region and two-band pattern in the  $\nu_{\text{CN}}$  region, individually, but in different positions, which may be accounted for by the distinct electronic effects between  $[\text{S}, \text{S-C-R}]^-$  and cysteine ligands.<sup>72</sup> Also, two particularly elegant model compounds  $[\text{Fe}(\text{CO})_2(\text{CN})_2(\text{SPh})_2]^{2-}$  (**20**) and  $[\text{Fe}(\text{CO})(\text{CN})_2(\text{S}, \text{S-C}_6\text{H}_4)]^{2-}$  (**21**) have been characterized by IR and X-ray diffraction, recently.<sup>73</sup> Scrutiny of the coordination chemistry of iron(II)-thiolate species  $[\text{Fe}^{\text{II}}(\text{CO})_x(\text{CN})_y(\text{SR})_z]^{n-}$  reveals that certain combinations of thiolate and cyanide ligands ( $3 \leq y + z \leq 4$ ) ligated to the Fe(II) center provide significant stabilization to the iron(II)-thiolate cyanocarbonyl species  $[\text{Fe}^{\text{II}}(\text{CO})_x(\text{CN})_y(\text{SR})_z]^{n-}$ .<sup>74,75</sup>

## 3 UREASE

### 3.1 Background

The metalloenzyme urease catalyzes the hydrolysis of urea to ammonia and carbamate (equation 1).<sup>76</sup>

The X-ray crystallographic studies of the enzyme isolated from *Klebsiella aerogenes* reveals an active site composed of a dinickel center with 3.5-Å Ni···Ni separation. A schematic view of the active site of urease isolated from *K. aerogenes* is

**Figure 2** A schematic drawing of the active site of urease isolated from *K. aerogenes*.<sup>77–79</sup>

shown in Figure 2.<sup>77,78</sup> The two nickel ions are bridged by a carboxylate group of a carbamylated lysine residue (see **Metal-mediated Protein Modification**) and one water molecule or hydroxide ion.<sup>77–81</sup> The geometry around one nickel ion (Ni(1)) is best described as a distorted square pyramidal with further coordination of two histidine residues from the protein and one terminally coordinated water molecule; the position is only partially occupied by a water molecule and considered to be a likely candidate for binding urea in the catalysis. One terminally coordinated water molecule, one additionally ligated aspartate residue, and two histidine residues complete the coordination spheres of the second nickel ion (Ni(2)), resulting in a pseudooctahedral geometry for Ni(2). The nickel centers are in the stable diamagnetic Ni(II) state; thus the role of Ni in urease may be essentially catalytic without necessarily redox chemistry.

Urease catalyzes hydrolysis of urea to ammonia and carbamate at a rate at least  $10^{14}$  times faster than the spontaneous hydrolysis rate of urea in aqueous solution between pH 2 to 12.<sup>82,83</sup> The stability of urea is attributed to its resonance energy, which has been estimated at 30–40 kcal mol<sup>-1</sup>.<sup>84</sup> The zwitterionic resonance forms of urea donate electrons to the carbonyl carbon, causing it to be less reactive toward nucleophiles.

It is considered that urease employs such an unsymmetric dinuclear core to promote the concerted binding of the substrate at one nickel center and a hydroxide nucleophile at the other nickel center.<sup>80</sup> There are many studies of urease<sup>77–85</sup> and model dinickel complexes to elucidate the relationship between the structure and function of the dinickel active site.<sup>86–91</sup> The generally accepted mechanism has suggested that both nickel ions are involved in the hydrolysis of urea. Several key features of the molecular geometry at the active site are essential for the function of the enzyme: (i) an open coordination site at each nickel center, (ii) the generation of a Ni-bound hydroxyl group resulting from removal of a proton from coordinated water by the assistance of a basic histidine residue located in proximity to the dinickel core, and (iii) polarization of the urea substrate through oxygen binding

**Scheme 4** A mechanism for the hydrolysis of urea by urease

to one Ni center followed by nucleophilic attack by a Ni-bound hydroxyl group.<sup>77–92</sup> The choice of Ni for this catalytic hydrolysis reaction may be attributed to the high affinity of the urea-Ni binding and the stability of the urease Ni-containing active site. The proposed catalytic cycle of ureases is shown in Scheme 4.<sup>80</sup>

### 3.2 Structural and Functional Models

Numerous dinickel complexes have been reported as models for urease. As depicted in Scheme 5, a dinickel complex  $[\text{Ni}_2(\mu\text{-OH})(\mu\text{-H}_2\text{O})(\text{bdptz})(\text{H}_2\text{O})_2][\text{OTs}]_3$  is capable of hydrolyzing a bound amide substrate by intramolecular nucleophilic attack of a coordinated hydroxide ion, either from a bridging position or from a transient terminally bound form.<sup>86</sup> This amide hydrolysis mimics the hydrolysis of urea by urease in that a hydroxide nucleophile is generated by the dinickel center, and the coordination of the substrate to the dinickel center as well as a nickel-bound hydroxide ion serving as the nucleophile are crucial to hydrolysis. Protonation of the amine group by an acidic residue in the active-site results in loss of ammonia.

A number of dinickel urease models with urea bound to the dinickel center implicate preferential binding of urea via the carbonyl oxygen atom;<sup>87–91</sup> this coordination mode is

believed to be a species formed for the urea substrate binding to Ni(1) by replacing the terminally bound water molecule in the catalytic cycle of urease.<sup>77,79</sup> In addition to these model complexes, catalytic ethanolsis of urea by a  $(\mu\text{-alkoxo})(\mu\text{-carboxylato})\text{dinickel(II)}$  complex, presumably taking place via nucleophilic attack of ethanol solvent on coordinated urea, was also reported.<sup>88,90</sup>

An alternative mechanism for the urease-catalyzed hydrolysis of urea is hydrolysis of urea to ammonia and carbon dioxide through formation of a cyanate intermediate.<sup>92–95</sup> This reaction proceeds via a pathway, which is distinct from the proposed enzymatic hydrolysis of urea shown in Schemes 4 and 5. Upon heating, a dinickel complex  $[\text{Ni}_2(\mu\text{-OH})(\mu\text{-urea})(\text{bdptz})(\text{urea})(\text{CH}_3\text{CN})][\text{ClO}_4]_3$  containing a bridging urea molecule promotes the hydrolysis of urea in a two-step reaction; a molecule of ammonia is eliminated from urea with concomitant formation of a cyanate intermediate and, subsequently, the cyanate-containing intermediate is hydrolyzed by an external water molecule upon further heating. In this catalytic reaction, it is proposed that the coordinated hydroxide ion is not sufficiently nucleophilic to hydrolyze the coordinated urea molecule. On the contrary, the coordinated hydroxide ion serves as a base aiding in the deprotonation of urea to favor elimination. These results establish the precedence for hydrolysis of urea via a cyanate

**Scheme 5** A mechanism for the hydrolysis of urea. (Reprinted from *J. Am. Chem. Soc.*, 1999, **121**, 11751–11757. © 1999 American Chemical Society)

intermediate for the urease-catalyzed hydrolysis of urea, as shown in Scheme 6.<sup>92</sup>

In addition, urease is inhibited by a variety of agents including fluoride<sup>96</sup> and disulfides,<sup>97</sup> as observed recently in the acetohydroxamate-inhibited C319A variants of *K. aerogenes* urease.<sup>78</sup> It is proposed that this mode of inhibition involves coordination of the inhibitor to only one nickel center, while another involves the inhibitor bridging the dinickel center. Urease is slowly inhibited by fluoride in both the presence and absence of substrate, and fluoride binding rates are directly proportional to inhibitor concentration. Fluoride inhibition is pH-dependent due to a protonation

event linked to fluoride dissociation. That fluoride binding is pH-independent suggests that fluoride anion, not HF, is the actual inhibitor.<sup>96</sup> Reaction of the model complex  $[\text{Ni}_2(\text{OAc})_3(\text{urea})(\text{tmen})_2][\text{OTf}]$  ( $\text{OAc} = \text{CH}_3\text{COO}^-$ ) with acetohydroxamic acid (AHA) gives the monobridged hydroxamate complex  $[\text{Ni}_2(\text{OAc})_2(\text{AHA})(\text{urea})(\text{tmen})_2][\text{OTf}]$ , a close model of the proposed mode of urease inhibition by hydroxamic acids.<sup>78,89,98</sup> In particular, only one bridging hydroxamate for the inhibited urease was suggested.<sup>98</sup>

#### 4 CARBON MONOXIDE DEHYDROGENASE/ACETYL COENZYME A SYNTHASE (CODH/ACS)

##### 4.1 Background

Carbon monoxide dehydrogenase/acetyl coenzyme A synthase (CODH/ACS) describes two different classes of enzymes; carbon monoxide dehydrogenase (CODH) isolated from *Rhodospirillum rubrum* or *Carboxydotherrmus hydrogenoformans* reversibly oxidizes CO to  $\text{CO}_2$  according to equation (2), and the bifunctional CODH/ACS enzyme from *Moorella thermoacetica* catalyzes the reversible reduction of  $\text{CO}_2$  to CO (CODH) and acetyl coenzyme assembly/disassembly (ACS) (equation 3).<sup>99–101</sup>

**Scheme 6** A mechanism for the hydrolysis of urea. (Reprinted from *J. Am. Chem. Soc.*, 2000, **122**, 9172–9177. © 2000 American Chemical Society)

**Figure 3** (a) A schematic drawing of the active-center C-cluster of CODH isolated from *R. rubrum* or *C. hydrogenoformans*.<sup>102–104</sup> (b) A schematic drawing of the active site of the ACS enzyme isolated from *C. thermoaceticum*.<sup>104–106</sup>

Recent X-ray crystallographic studies indicated that the dimeric CODH isolated from *R. rubrum* or *C. hydrogenoformans* contains two  $[\text{Fe-NiFe}_3\text{S}_4]$  C-clusters, two conventional cysteine-ligated  $[\text{Fe}_4\text{S}_4]$  B-clusters, and a D-cluster that bridges the two subunits.<sup>102–104</sup> The B-cluster is involved in electron transfer and the *R. rubrum* enzyme catalyzes the biological oxidation of CO at the C-cluster. The active-center C-cluster is composed of the mononuclear Fe site and the four-metal cubane cluster  $[\text{NiFe}_3\text{S}_4]$  bridged by cysteine and one of the sulfides of the cube, as shown in Figure 3(a). Recently, the crystallographic characterization of the ACS enzyme isolated from *C. thermoaceticum* revealed an unprecedented hexametallic active site, a cuboidal  $[\text{Fe}_4\text{S}_4]$  unit linked via cysteine to a binuclear  $[\text{CuNi}]$  subcluster. The proximal copper atom is coordinated by three cysteine sulfur atoms and the unidentified fourth ligand. The distal Ni is in a square-planar environment with two amide nitrogens (deprotonated protein backbone) and two cysteine thiolates coordination (Figure 3(b)).<sup>104–106</sup>

The amount of Cu in CODH/ACS directly correlates with ACS activity. However, Cu is not the only metal that can occupy the Cu site. The negative correlation between Zn content and ACS activity suggests that Zn can replace Cu and inhibit the enzyme.<sup>106</sup> In contrast, the active-site structure from *M. thermoacetica* ACS enzyme (an  $\alpha_2\beta_2$  tetramer) shows that the two  $\alpha$ -subunits display different conformations (open and closed conformations). One  $\alpha$ -subunit contains one Zn, located in the proximal site, and one Ni at its active-site metal cluster ( $\alpha$ -closed form), while the A-cluster of the other  $\alpha$ -subunit contains two Ni ions at the corresponding positions ( $\alpha$ -open form).<sup>107,108</sup> These investigations also demonstrate that Cu-containing ACS is inactive and only the A-cluster containing two Ni ions are responsible for the observed catalytic activity.<sup>107,108</sup> Such a  $\text{Ni}(\mu\text{-Cys})_3$  low-coordinate site may be susceptible to demetalation by 1,10-phenanthroline, accounting for the observation that 1,10-phenanthroline removes some of the Ni in the protein resulting in loss of ACS activity and the correlated spectroscopic signals.<sup>107,108</sup>

The CODH from *R. rubrum* catalyzes both the oxidation of CO as well as the reduction of  $\text{CO}_2$ , and does not synthesize acetyl CoA. A mechanism for CO/ $\text{CO}_2$  oxidation catalyzed

by the C-center of CODH has been proposed in which the C-center can be stabilized in three states. The detailed electronic structures of the various  $[\text{Fe-NiFe}_3\text{S}_4]$  oxidation states remain ambiguous. As shown in Scheme 7, CO binding to the Fe site and subsequent nucleophilic attack of  $\text{OH}^-$  on the CO or CO insertion into the Ni–OH bond leads to the release of  $\text{CO}_2$ . In this catalytic cycle, it is proposed that CO is bound to a unique Fe site of the C-cluster and at least two sites of the C-cluster are essential for the catalytic interconversion of CO and  $\text{CO}_2$ . Meanwhile, the Ni ion is proposed to be redox active.<sup>109–111</sup> On the basis of recent studies, a model for the mechanism of  $\text{CO}_2$  reduction was proposed. In this model, fully oxidized CODH ( $[(\text{CO})_L\text{Fe}^{2+}\text{-Ni}^{2+}]^{4+}$ ) and CODH at the  $\text{C}_{\text{red1}}$  state ( $[(\text{CO})_L\text{Fe}^{3+}\text{-Ni}^{2+}\text{-H}^-]^{4+}$ ) are unable to reduce  $\text{CO}_2$  to CO.  $\text{CO}_2$  reduction only occurs effectively when the putative  $[\text{Fe-NiFe}_3\text{S}_4]$  subcluster is fully reduced  $[(\text{CO})_L\text{Fe}^{2+}\text{-Ni}^{2+}\text{-H}^-]^{3+}$  ( $\text{C}_{\text{unc}}$  state).<sup>111–114</sup> The B-cluster mediates electron flow from the C-center to the external electron acceptors in *R. rubrum* CODH and to the A-cluster via the 13.8-Å-long hydrophobic channel in *M. thermoacetica* CODH.<sup>115</sup> Cyanate, thiocyanate, and azide have been shown to bind to the C-center and inhibit CO oxidation.<sup>116</sup>

In addition to the CO oxidation occurring at the C-center, the *M. thermoacetica* enzyme is also capable of catalyzing the synthesis of acetyl coenzyme A at the A-center located in the  $\alpha$  subunit.<sup>117</sup> The bifunctional enzyme CODH/ACS plays a central role in the Wood–Ljungdahl pathway of autotrophic  $\text{CO}_2$  fixation.<sup>99</sup> In the acetate-production pathway, one  $\text{CO}_2$  molecule is reduced to a methyl group in a set of enzymatic reactions. CO generated from  $\text{CO}_2$  reduction at the C-cluster travels through a 70-Å channel and binds to Cu to generate a paramagnetic species  $\text{NiFeC}$  observed by FTIR and EPR spectroscopy.<sup>105,118–120</sup> The proposed mechanism of acetyl CoA synthesis is shown in Scheme 8. Methylation of Ni by the methyl group of protein-bound methylcob(III)amide yields cob(I)amide and a diamagnetic state, a transient methyl-Ni(III) species.<sup>121,122</sup> Electron transfer from  $[\text{Fe}_4\text{S}_4]^+$  to the transient methyl-Ni(III) species generates methyl-Ni(II). The reaction of CO and the methyl group could proceed through an alkyl migration yielding an acetyl-metal-bound intermediate, and then  $\text{HSCoA}$  is deprotonated and acetylated.<sup>123</sup>

**Scheme 7** A proposed mechanism for CO/CO<sub>2</sub> oxidation catalyzed by the C-center of CODH. (Reprinted from *J. Am. Chem. Soc.*, 1996, **118**, 10 429–10 435. © 2003 American Chemical Society)

## 4.2 Structural Models

There are several bimetallic systems bearing a stoichiometric and structural resemblance to the bimetallic site of ACS. Structures of the binuclear complexes (**22**) and (**23**) show that the adjacent thiolate donors of the [N<sub>2</sub>S<sub>2</sub>]Ni motif can serve as a chelate in coordinating to a single Cu metal. Reactivity studies confirm that the binuclear complexes (**22**) and (**23**) bind CO, and subsequently, generate the respective mononuclear species, [N<sub>2</sub>S<sub>2</sub>]Ni and [PhTt<sup>t</sup>Bu]Cu(CO) resulting from the rupture of the thiolate bridges,<sup>124,125</sup> as observed in the paramagnetic NiFeC species. The NiFeC species, produced from reductive carbonylation of the A-cluster, indicates Cu-CO and acetyl-Cu intermediates characterized by EPR, IR, and Mössbauer studies.<sup>105,126–128</sup> The dimeric ‘staircase’ structure

[Cu<sub>2</sub>{NiS<sub>2</sub>N<sub>2</sub>}]<sub>2</sub><sup>2+</sup> (**24**), structurally analogous to the ACS active site, was obtained by reaction of [Cu(NCMe)<sub>4</sub>]<sup>+</sup> and the nickel hexamethylated diamino dithiolate ([NiS<sub>2</sub>N<sub>2</sub>]).<sup>129</sup> Treatment of complex (**24**) with PR<sub>3</sub> (R = *i*Pr, NMe<sub>2</sub>) yielded the bimetallic derivative [{(R<sub>3</sub>P)(MeCN)Cu}{NiS<sub>2</sub>N<sub>2</sub>}]<sup>+</sup> (**25**).

**Scheme 8** A proposed mechanism of acetyl CoA synthesis. (Reprinted from *Proc. Natl. Sci. U.S.A.*, 2003, **100**, 3689–3694. © 2003 National Academy of Science, U.S.A.)

Relevant to the conflicting reports of copper versus nickel requirements for enzyme activity,<sup>106,130</sup> biochemical studies demonstrated the existence of a labile nickel associated with the  $\alpha$  subunit of ACS/CODH.<sup>131</sup> Very recently, model studies on a metal-ion capture of a peptide-backbone, nonlabile [NiN<sub>2</sub>S<sub>2</sub>] (26) unit have established the capability of such a nickel dithiolate to bind exogenous metals. A qualitative ranking of the binding ability of complex (26) with Zn<sup>2+</sup>, Cu<sup>+</sup>, and Ni<sup>2+</sup> was established by a metal-ion displacement experiment (Zn<sup>2+</sup> < Ni<sup>2+</sup> < Cu<sup>+</sup>), as shown in Scheme 9.<sup>132</sup> A concept that the chemically most reasonable dinickel ACS

**Scheme 9** The binding ability of complex (26) with  $\text{Zn}^{2+}$ ,  $\text{Cu}^{+}$  and  $\text{Ni}^{2+}$

active site could be compromised by copper replacement has been derived from the lability study of both Zn and Ni bound by the model complex (26). This accounts for the possibility of exclusion of inappropriately associated metals to ultimately achieve functioning active sites in the nickel enzyme.<sup>133</sup>

On the other hand, the A-cluster in the ACS subunit of the protein is also proposed to bind CO via the Ni atom prior to CO migratory insertion into a  $\text{H}_3\text{C-Ni}$  bond.<sup>99,134</sup> The four-coordinate  $[(\text{bipy})\text{Ni}(\text{CH}_3)(\text{SR})]$  and  $[(\text{bipy})\text{Ni}(\text{SCH}_2\text{CH}_2\text{CH}_2)]$  complexes provide a possible model for CO insertion into the  $\text{H}_3\text{C-Ni}$  bond yielding the stable acetylthiolatonicel,<sup>135</sup> and thialactones under CO atmosphere,<sup>136</sup> respectively.

## 5 METHYL COENZYME M REDUCTASE

### 5.1 Background

Methyl coenzyme M reductase (MCR) is the enzyme responsible for the microbial formation of methane

by the methanogens, a class of strictly anaerobic archaeobacteria.<sup>137–140</sup> A key component of the active site of MCR is cofactor  $\text{F}_{430}$  (Figure 4), a nickel tetrahydrocorphinoid cofactor.

X-ray crystallographic studies reveal that MCR is composed of three different subunits in an  $\alpha_2\beta_2\gamma_2$  arrangement containing tightly bound 2 mol of the nickel porphrinoid

**Figure 4** A schematic drawing of the active site of MCR<sup>139,141–143</sup>

**Scheme 10** The production of methane and CoM-S-S-CoB catalyzed by methyl coenzyme M reductase

$\text{F}_{430}$ , and cofactor  $\text{F}_{430}$  forms the base of a narrow well accommodating the two substrates.<sup>141–143</sup> The phosphate group of HS-CoB binds at the upper lip of the well with its thiol group located 6 Å from the central Ni atom of  $\text{F}_{430}$ .<sup>141–143</sup> Synthesis of methane and the heterodisulfide CoM-S-S-CoB is achieved by two-electron reduction of MeS-CoM (2-(methylthio)ethanesulfonate) by HS-CoB (7-thioheptanoylthreonine phosphate) (Scheme 10). HS-CoB serves as the electron donor, and the heterodisulfide CoM-S-S-CoB is the product of the oxidative half-reaction.<sup>137–140</sup>

A variety of nickel oxidation states (Ni(I), low-spin Ni(II), high-spin Ni(II) and Ni(III)) have been characterized for  $\text{F}_{430}$ .<sup>141–146</sup> High-resolution X-ray crystallographic structures of EPR-silent high-spin Ni(II) forms of the inactive enzyme show that the Ni sites are six-coordinate with four tetrapyrrole nitrogen ligands in the plane, the carbonyl oxygen of a side-chain glutamine in the lower axial position, and the thiolate of  $^-S\text{-CoM}$  as the upper ligand in the  $\text{MCR}_{\text{red1-silent}}$  and  $\text{MCR}_{\text{ox1-silent}}$  states. A sulfonate oxygen from the CoM-S-S-CoB disulfide is the upper axial ligand in  $\text{MCR}_{\text{silent}}$  state.<sup>141–143</sup> For the enzyme to be active, the prosthetic group has to be in the Ni(I) oxidation state, and EPR, ENDOR, resonance Raman, and X-ray absorption studies demonstrate that both the  $\text{MCR}_{\text{ox1}}$  and  $\text{MCR}_{\text{red1}}$  are Ni(I) states.<sup>145–147</sup> Meanwhile, XAS results indicate that the Ni(I) sites in both  $\text{MCR}_{\text{ox1}}$  and  $\text{MCR}_{\text{red1}}$  are six-coordinate. On the basis of X-ray crystallographic structures of two Ni(II) inactive forms of the enzyme, a proposed catalytic mechanism is shown in Scheme 11.<sup>141</sup> A nucleophilic attack of coenzyme  $\text{F}_{430}$  Ni(I) form on the methyl group of CoM leads to a Me-Ni(III) complex (Scheme 11a). Here the nucleophilic reaction of Ni(I) resulting in the activation of the carbon–sulfur bond is presumed to be facilitated by protonation of MeS-CoM. Electron transfer from the protonated CoM to the strongly oxidative Ni(III) results in the formation of a CoM thiyl radical and Me-Ni(II) intermediate. Protonolysis of the methyl group of the Me-Ni(II) intermediate, the concomitant coupling of the CoM thiyl radical and the thiolate group of CoB, accompanied by electron transfer from the generated disulfide

anion radical to the Ni(II), generates methane, CoM-S-S-CoB and the second Ni(I) intermediate (Scheme 11b–c). It is proposed that a coordination of the sulfonate oxygen to nickel is prevented when nickel is present as nucleophilic Ni(I). The repulsion between Ni(I) and the sulfonate oxygen molecules might act as a driving force to push the heterodisulfide out of the channel (Scheme 11d).<sup>141</sup>

Density functional theory (DFT) computations suggest that either Ni(I) or Ni(III) formulations for  $\text{MCR}_{\text{ox1}}$  states are conceivable.<sup>148,149</sup> EPR/ENDOR studies and analyses of the XANES/EXAFS/RR data indicate that both the  $\text{MCR}_{\text{ox1}}$  and  $\text{MCR}_{\text{red1}}$  states are best described as a hexacoordinate Ni(I) species, and that the main difference between  $\text{MCR}_{\text{ox1}}$  and  $\text{MCR}_{\text{red1}}$  is a change of one axial ligand from a S donor to an O/N donor.<sup>149,150</sup> Studies also imply that conversion from  $\text{MCR}_{\text{ox1}}$  to  $\text{MCR}_{\text{red1}}$  involves conformational rearrangements resulting from a two-electron reversible reduction of the hydrocorphin ring of  $\text{F}_{430}$ , and these changes trigger the activation to a  $\text{MCR}_{\text{red1}}$  state that can react productively with the methyl group of MeS-CoM.<sup>148–150</sup> In addition, recent studies implicate that the six-coordinate Ni(I) centers in the  $\text{MCR}_{\text{ox1}}$  and  $\text{MCR}_{\text{red1}}$  states exhibit markedly different reactivities and the enhanced reactivity of  $\text{MCR}_{\text{red1}}$  is due to the replacement of a relatively exchange-inert thiol ligand in  $\text{MCR}_{\text{ox1}}$  with a weakly coordinating upper axial ligand in  $\text{MCR}_{\text{red1}}$  that can be easily replaced by incoming ligands.<sup>148–150</sup> Furthermore, HS-CoB is required as a second substrate and induces a change forcing the real substrate, MeS-CoM, and Ni(I) of the prosthetic group to interact in the active enzyme  $\text{MCR}_{\text{red1}}$ .<sup>151–154</sup>

## 5.2 Structural and Functional Models

$\text{Ni}^{\text{I}}\text{-F}_{430}$  reacting directly with MeS-CoM before/after the substrate activation, the role of the thiol cofactor HS-HTP, and the reason(s) for the enzyme specifically directing the C–S bond cleavage to the Me–S bond of Me-CoM are the principal questions to be resolved to understand how the enzyme methyl coenzyme M reductase functions.

**Scheme 11** A proposed catalytic mechanism for the formation of methane and CoM-S-S-CoB by methyl coenzyme M reductase

Numerous mononuclear Ni complexes have been synthesized to investigate the possible mechanism for the formation of disulfide and methane catalyzed by the enzyme.<sup>155–159</sup> Two models that are perhaps relevant to the mechanistic situation of MCR are complexes (27) and (28) that feature square-planar

Ni site coordinated through both the thiolate and the methyl thioether sulfur atoms,<sup>155</sup> and four N-donors,<sup>156</sup> respectively.

As interpreted in Scheme 12,<sup>155</sup> a sterically shielded, bifunctional model substrate containing a methyl thioether and sulfhydryl functional group could form a five-membered

**Scheme 12** A proposed mechanism for methane formation involving C–S bond cleavage. (Reprinted with permission from *Chem. – Eur. J.*, 2000, **6**, 3508–3516. © 2000 John Wiley & Sons, Ltd)

**Scheme 13** A mechanism for methane formation involving a Ni–Me intermediate

cyclic sulfuranyl radical when this complex was irradiated with light of  $\lambda > 300$  nm. The role of irradiation is interpreted as the formation of a  $\text{Ni}^{\text{I}}$ -thiyl radical pair upon excitation of a charge-transfer band of the  $\text{Ni}^{\text{II}}$ -dithiolate compound (Scheme 12a). Cyclization of the photochemically generated thiyl radical yields a sulfuranyl radical accompanied by transfer of a methyl group to  $\text{Ni}(\text{I})$  to produce a methyl- $\text{Ni}(\text{II})$  intermediate (Scheme 12b–c). Here the addition of a thiyl radical to the sulfur atom of the thioether giving a sulfuranyl radical intermediate is the central step. The methyl- $\text{Ni}(\text{II})$  intermediate dissociates to methane and complex **(27)** through protonation. In particular, the cleavage of the carbon–sulfur bond of the aliphatic sulfide described in Scheme 12 occurred only in the presence of nickel and after excitation of the  $\text{Ni}^{\text{II}}$ -thiolate charge-transfer band.

A similar, but bimolecular, photoinduced reaction was observed on the basis of the nickel complex **(28)**,  $p$ -toluene thiolate, and thioanisole reactants to generate methane and disulfide.<sup>156</sup> The thiyl radical and  $\text{Ni}(\text{I})$  complex was prepared by the photolysis of the  $\text{Ni}(\text{II})$  complex **(28)** and  $p$ -toluene thiolate anion in acetonitrile solution. Upon irradiation ( $\lambda = 350$  nm) of the mixture of complex **(28)**,  $p$ -toluene thiolate ion, and thioanisole in acetonitrile under argon, gas chromatography-mass spectral analysis showed the formation of methane, ditolyl disulfide ( $\text{TolS}_2$ ), and a mixed disulfide  $\text{TolSSPh}$ . The proposed catalytic mechanism is depicted in

Scheme 13.<sup>156</sup> The catalytic reaction was proposed to go through a sulfuranyl radical by addition of a thiyl radical to the sulfur atom of the thioether MeSPh. Interestingly, these studies are consistent with the proposed mechanism of the enzyme; the thiyl radical of cofactor HS-CoB resulting from one-electron reduction of F<sub>430</sub> by <sup>-</sup>S-CoB couples with Me-CoM to afford the sulfuranyl radical, CoB-S-S-(Me)-CoM. The sulfuranyl radical transfers a methyl radical to Ni<sup>I</sup>-F<sub>430</sub> to generate Me-Ni<sup>II</sup>-F<sub>430</sub> and the heterodisulfide CoM-S-S-HTP.<sup>160,161</sup>

## 1 INTRODUCTION

The organometallic chemistry of nickel has experienced rapid growth over the past decade. A number of exciting new areas have emerged, such as the reactivities of Ni(0)-carbene complexes (see **Carbene Complexes**) and the polymerization of olefins catalyzed by nickel complexes (see **Oligomerization & Polymerization by Homogeneous Catalysis**) of nitrogen-based ligands. In addition, the traditionally rich area of Ni-catalyzed organic transformations has undergone major developments that have expanded the scope of their applications. Altogether, the synthesis and characterization

of new complexes, the discovery of new reactions, and the development of new catalytic processes has meant that a bright future awaits this area of inorganic chemistry.

The material presented in this chapter is organized in various sections according to the main ligands coordinated to the Ni atom or the type of reaction being discussed. Thus, there will be a section on the complexes of allyl, Cp, Ind, and Tp ligands (see **Tris(pyrazolyl)borates**). The increasing number of reports that have appeared on these complexes over the past decade show that they have a rich array of interesting structural and reactivity features. The main structural and bonding properties of these complexes are presented and their major reactivities are outlined.

Section 3 is devoted to the complexes of hydride, alkyl, alkenyl, and silyl ligands. Hydrido (see **Hydride Complexes of the Transition Metals**) and alkyl complexes of most transition metals, and in particular those of nickel, are often involved in many catalytic processes of commercial importance; therefore, an in-depth understanding of the fundamental reactivities of these complexes is crucial to expanding their practical applications. Silyl complexes are involved in the transformations of organosilicon compounds, and for this reason their basic reactivities and structural properties are of interest.

The chemistry of zerovalent nickel complexes will be discussed in Section 4. One of the most exciting developments in this area is the recent introduction of N-heterocyclic carbene ligands. Ni complexes of these ligands have been shown to be important catalysts and reagents for a number of important organic transformations. This section will describe briefly the practical methods for preparing Ni-carbene complexes and will outline some of the catalytic reactions promoted by these complexes. This section will also describe the preparation and reactivities of other types of Ni(0) complexes.

Section 5 is dedicated to discussing the polymerization and copolymerization of olefins. This aspect of the chemistry of Ni complexes has experienced a phenomenal growth and development over the past decade, beginning with the discovery of a family of diimine complexes that catalyze the polymerization of aliphatic olefins. A series of new and highly efficient catalysts were introduced in rapid progression, a great deal of new chemistry has been discovered, and a number of industrial processes have been developed on the basis of these nickel complexes. In contrast, nickel-based catalysts are not very efficient in the alternating copolymerization of CO/ethylene, but studies of this reaction have revealed very interesting patterns of reactivity which appears to be fairly unique to nickel.

The last section of this chapter is dedicated to an overview of a number of coupling reactions catalyzed by nickel complexes. Thus, we will discuss the emergence of new strategies for the efficient cross-coupling of alkyl halides with organozinc and Grignard reagents, as well as the coupling of dienes with  $\text{CO}_2$ .

## 2 ALLYL, CYCLOPENTADIENYL, INDENYL, AND TRIS(PYRAZOLYL)BORATE COMPLEXES

### 2.1 Allyl Complexes

Allyl complexes (*see Allyl Complexes*) have occupied an important position in the development of the organometallic chemistry of nickel. Thus, allylnickel complexes have had numerous applications in organic synthesis (e.g. nucleophilic attack on coordinated allyl ligands) and have been identified as key intermediates in the oligomerization and cyclization of olefins and dienes; moreover, the  $\eta^3/\eta^1$  rearrangements of allylnickel species has helped explain the facile isomerization of olefins in the presence of nickel complexes. The vast majority of allylnickel complexes are 4-coordinate, 16-electron complexes of the type (allyl)Ni(L)X, [(allyl)NiLL']<sup>+</sup>, or (allyl)<sub>2</sub>Ni (L and X are neutral and anionic two-electron donor ligands, respectively). A recent report has shown, however, that formally 5-coordinate and 18-electron species are thermally stable but highly reactive catalysts (turnover frequency of up to 2000/min) for the oligomerization of styrene (equation 1).<sup>1</sup> The unusual coordination of three SbPh<sub>3</sub> ligands and their great lability are due, presumably, to the longer, less robust Ni–Sb bonds.

In comparison to the allyl complexes, the analogous cyclopentadienyl (Cp) complexes, with the exception of nickelocene, Cp<sub>2</sub>Ni (*see Nickelocene*), have played a less prominent role. However, there has been a resurgence of interest over the past decade in the reactivities of CpNi complexes and this interest has extended into the chemistry of the analogous indenyl (Ind) and tris(pyrazolyl)borate (Tp) (*see Tris(pyrazolyl)borates*) complexes. Some of the major developments in this area are outlined in the following sections.

### 2.2 Cp Complexes

The reaction of nickelocene with primary phosphines has allowed the preparation of the phosphido-bridged dimers (1); deprotonation and methylation of the phosphido moiety results in the formation of the methylated derivatives (2) (Scheme 1).<sup>2</sup>

A large series of pentamethylcyclopentadienyl (Cp\*) derivatives have been prepared by reacting PEt<sub>3</sub> with

Scheme 1

Scheme 2

Cp\*Ni(acac), which was shown to be a paramagnetic, 18-electron, spin-equilibrium molecule,<sup>3</sup> followed by addition of a variety of reagents (e.g. MeLi, LiBr, PR<sub>3</sub>, NaOMe, etc.).<sup>4,5</sup> Systematic structural studies of these complexes have led to interesting generalizations about the haptotropic distortions observed in the Cp\* ring; these distortions range from a symmetrical allyl-ene to diene-yl type distortions (Scheme 2). In addition, the impact on the Ni–Cp interactions of the ligand trans influence exerted by the other auxiliary ligands has been discussed and the following approximate trans influence order has been suggested: alkyl, hydride > phosphine, methoxide > arylamide, aryloxide, arylthiolate, bromide. A study of the Ni-amido derivatives with Brønsted acids HX has led to the observation that the Ni–X bonds have a significant electrostatic component.

A number of interesting complexes bearing hemilabile (dimethylamino)ethyl-Cp has been reported. The tethered, hemilabile amino moiety either coordinates to the Ni center or to an unsaturated group 13/14 ligand (Scheme 3); in the absence of such unsaturated ligands or when the Ni center is coordinatively saturated, the amino moiety remains dangling.<sup>6–8</sup>

### 2.3 Indenyl Complexes

An extensive series of indenyl complexes has been prepared and their structural and reactivity features studied in-depth.<sup>9</sup> The detailed characterization, in solution and solid state, of complexes IndNi(L)X (L = PR<sub>3</sub> and N-heterocyclic carbenes; X = halides, imidates, alkyl, alkynyl, thienyl, triflate, etc.) and [IndNi(PR<sub>3</sub>)L]<sup>+</sup> (L = PR<sub>3</sub>, MeCN, CN(*t*-Bu)) has allowed an analysis of the factors affecting the Ni–Ind interaction.<sup>10–12</sup> As was seen for the Cp\* complexes discussed

Scheme 3

Scheme 4

above, the trans influence differences of the ligands L and X is responsible for the Ind–Ni bonding mode: ligands of widely different trans influence values (e.g. PPh<sub>3</sub> and Cl) lead to a nonsymmetrical hapticity approaching  $\eta^1, \eta^2$ -Ind, whereas ligands of similar trans influence values (e.g. PPh<sub>3</sub> and Me) give a symmetrical interaction ( $\eta^5 - \eta^3$ , Scheme 4).<sup>13</sup> Interestingly, the more strongly donor and covalent ligands such as Me and PPh<sub>3</sub> result in stronger Ni–Ind interaction (less slip-folded, shorter Ni–C bonds), whereas weaker and more ionic ligands such as halides result in weaker Ni–Ind interactions (large slip-fold distortions, longer Ni–C bonds).<sup>14</sup> In general, these Ind complexes appear to be less stable and more reactive than the corresponding Cp\* analogues.

The neutral Ni–Cl or Ni–R complexes undergo associative ligand substitution reactions (Scheme 5, *see Associative Substitution; Mechanisms of Reaction of Organometallic Complexes*),<sup>15</sup> and react with methylaluminoxane (MAO) to generate intermediates that polymerize ethylene to high MW poly(ethylene),<sup>16</sup> and alkynes to *cis*, *transoid*-poly(alkynes) (Scheme 6).<sup>17–20</sup>

On the other hand, the cationic bis(phosphine) complexes [IndNi(PR<sub>3</sub>)<sub>2</sub>]<sup>+</sup> and the highly electrophilic, in situ generated cations [Ind(PR<sub>3</sub>)]<sup>+</sup> catalyze the dimerization of ethylene<sup>21</sup> and oligo- and polymerization of other olefins (Scheme 7).<sup>22,23</sup>

The reaction of PhSiH<sub>3</sub> with the Ni–Me precursors has been shown to result in the formation of oligosilanes (PhSiH)<sub>n</sub>.<sup>24</sup> The initial step of this reaction is believed to go through a concerted  $\sigma$ -bond metathesis ( $K_H/K_D \sim 10$ ), but multiple intermediates are formed in the later stages of the catalysis, some of which result from the reductive elimination (*see Reductive Elimination*) of the indenyl ligand (Scheme 8).<sup>25</sup>

The indenyl complexes are also efficient precatalysts for the hydrosilylation (*see Hydrosilylation*) of olefins, alkynes, and ketones.<sup>26</sup> This reaction is believed to involve a hydrido intermediate, which can be generated initially via different routes (Scheme 9).

A few interesting dinuclear complexes bearing CpCMe<sub>2</sub>Ind or IndCMe<sub>2</sub>Ind ligands have also been prepared (Scheme 10),<sup>27</sup> as have complexes bearing aminoindenyl

Scheme 5

Scheme 6

Scheme 7

Scheme 8

### Scheme 9

### Scheme 10

ligands (Scheme 11); the hemilabile nature of the amine moiety in the latter complexes facilitates a number of interesting catalytic reactions.<sup>28–32</sup>

## 2.4 Tp Complexes

A recent report has shown that tris(pyrazolyl)borate (Tp) (*see Tris(pyrazolyl)borates*) complexes of Ni tend to form 5-coordinate, formally 18-electron complexes. The hapticity of the tris(pyrazolyl)borate ligand in these complexes appears to be more sensitive to the steric environment around the Ni center as opposed to the electronic factors (i.e. formal electron count of the complex).<sup>33</sup> Thus, the  $\eta^3$ -allyl derivative of tris{(3,5-*i*-Pr<sub>2</sub>-pyrazolyl)borate}NiR (**3**) displays a  $\kappa^3$ -coordination, whereas the  $\eta^3$ -prenyl derivative (**4**) adopts a  $\kappa^2$ -coordination

(Scheme 12); interestingly, carbonylation of the 4-coordinate complex ( $\kappa^3$ -Tp)Ni-Et (**5**) gave the 5-coordinate complex ( $\kappa^3$ -Tp)Ni(CO){C(=O)Et} (**6**) underlining the readiness with which extra pairs of electrons are accommodated in the presence of Tp ligands.

### 3 HYDRIDO, ALKYL, ALKENYL, AND SILYL COMPLEXES

### 3.1 Hydride Complexes

Nickel hydride (*see Hydrides*) species are thought to be involved in a number of catalytic reactions, and so an intimate knowledge of the thermodynamics of Ni-H

Scheme 11

Scheme 12

bonds (e.g. homolytic dissociation energy, acidity, etc.) can be valuable in understanding the mechanisms of their reactivities. A convenient method for determining metal hydride bond energies (*see Bonding Energetics of*

*Organometallic Compounds*) is based on a thermodynamic cycle that uses the  $\text{p}K_{\text{a}}$  values of the hydride complex and the one-electron reduction potentials of its conjugate base to estimate the free energies of all three M-H bond cleavage

reactions ( $\Delta G^\circ_{\text{H}^-}$ ,  $\Delta G^\circ_{\text{H}^\bullet}$ ,  $\Delta G^\circ_{\text{H}^+}$ ).<sup>34</sup> Thus, electrochemical and  $pK_a$  studies can help establish the energetics of the Ni–H bond in complexes such as  $[\text{HNi}(\text{diphosphine})_2]^+$ , whose  $pK_a$  values can be measured fairly accurately and whose conjugate bases,  $\text{Ni}(\text{diphosphine})_2$ , undergo two reversible, one-electron oxidations ( $\text{Ni}(\text{II})/\text{Ni}(\text{I})$ ,  $\text{Ni}(\text{I})/\text{Ni}(\text{0})$ ). A number of these studies have shown that more electron-donating diphosphine ligands and those with smaller bite angles (*see Bite Angle*) increase the hydride donor ability of the Ni–H bond; the acidities are also affected by the basicity of the ligand but not the bite angles.<sup>35</sup>

Moreover, it has been shown that a free-energy relationship exists between the  $E_{1/2}(\text{II/I})$  values and the hydride donor abilities ( $\Delta G^\circ_{\text{H}^-}$ ) of  $\text{Ni}(\text{diphosphine})_2$ ; this can be justified by considering that the  $E_{1/2}(\text{II/I})$  values reflect the energy of the LUMO (*see LUMO*) in  $[\text{Ni}(\text{diphosphine})_2]^{2+}$ . Since the LUMO in these complexes is the antibonding  $d_{x^2-y^2}$  orbital, which is the orbital involved in hydride transfer reactions, it stands to reason that the energy of this ligand (and the  $E_{1/2}(\text{II/I})$  value) should correlate with the hydride donor/acceptor properties of  $[\text{Ni}(\text{diphosphine})_2]^{2+}$ . The more electron-donating substituents on the ligands increase the energy of the LUMO and make the reduction potentials more negative; therefore,  $[\text{HNi}(\text{diphosphine})_2]^+$  becomes a better hydride donor. On the other hand, larger bite angles lead to greater tetrahedral distortion of the structures and lower the energy of the  $d_{x^2-y^2}$  orbital; the resulting reduction in the antibonding nature of the  $\text{P}_\sigma\text{--}d_{x^2-y^2}$  interaction increases the hydride acceptor properties of the complex. A free-energy relationship also exists between the  $E_{1/2}(\text{I/0})$  values of  $\text{Ni}(\text{diphosphine})_2$  and acidities ( $\Delta G^\circ_{\text{H}^+}$ ) of the corresponding  $[\text{HNi}(\text{diphosphine})_2]^+$ ; this can be justified by considering that, to a first approximation, the  $E_{1/2}(\text{I/0})$  values represent the energy of the HOMO (*see HOMO*), which would be expected to influence the basicity of  $\text{Ni}(\text{diphosphine})_2$ .

An interesting, and somewhat counter-intuitive, finding of the above studies is that the values of  $\nu(\text{Ni–H})$  obtained from IR spectra correlate best with  $E_{1/2}(\text{II/I})$  and  $\Delta G^\circ_{\text{H}^-}$  values; in other words, the stretching frequencies correspond more closely to the hydride transfer reaction (equation 2) than to the homolytic cleavage (*see Homolytic Cleavage*). Altogether, these findings demonstrate that  $E_{1/2}(\text{II/I})$  and  $E_{1/2}(\text{I/0})$  values measured for a given complex can give fairly accurate estimates of the  $pK_a$  values and the energetics of the corresponding Ni–H complex. This information is useful when selecting appropriate acids for generating Ni–H species by protonation and for predicting the stability of the Ni–H bond toward decomposition by deprotonation or formation of  $\text{H}_2$ .

### 3.2 Alkyl Complexes

The complex  $[\text{Li}(\text{THF})]_4[\text{Ni}_2(\text{CH}_3)_8]$  (**7**) is a rare example of simple, anionic Ni-alkylate complexes. It has been prepared by reacting excess MeLi with a Ni(II) complex bearing oxalic amidinate (oxam) ligands (equation 3).<sup>36</sup> The stability of this homoleptic (*see Homoleptic Compound*) methyl complex towards reductive elimination is thought to be due to ineffective stabilization of the resulting Ni(0) complexes by the oxam ligands, which are poor  $\pi$ -acceptors. The  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra of this compound show singlets for the  $\text{CH}_3$  (ca.  $-0.6$  ppm) and  $\text{CH}_3$  nuclei (ca.  $-6$  ppm), respectively. The geometry around each Ni center is square planar and the relatively long Ni–Ni distance of ca.  $3.17 \text{ \AA}$  indicates little or no bonding interaction. The methyl ligands occupy the vertices of a cube and the dimeric structure is maintained by Li–H–C  $\alpha$  agostic interactions ( $\text{Li–H} = 2.05\text{--}2.08 \text{ \AA}$ ;  $\text{Li–H–C} = 95\text{--}96^\circ$ ). The Ni–C (ca.  $1.99\text{--}2.01 \text{ \AA}$ ) and Li–C ( $2.34\text{--}2.37 \text{ \AA}$ ) distances are fairly symmetrical. These complexes are thought to offer a glimpse into the presumed intermediates of cross-coupling reactions between R–X and R'M (X = halide; M = Li, MgX).

### 3.3 Protonation of Ni–R Moieties

Protonation of organometallic complexes,  $\text{L}_n\text{M–R}$ , is a reaction of fundamental importance both in the industrial applications of organometallic complexes and also in

Scheme 13

bioinorganic chemistry. In principle, protonation can occur at either the metal center or the (formally anionic) R ligand; moreover, since the added proton can move rapidly between the two sites, determining the initial site of protonation is often a complicated task.<sup>37–39</sup> A number of recent studies have examined the kinetics of protonating a series of  $[L_3Ni-R]^+$  complexes ( $L_3$  = triphos;  $R$  = Me,  $\eta^3$ -allyl) with the following findings (Scheme 13).<sup>40,41</sup> The Ni center in the  $\eta^3$ -allyl derivative was found to be ca.  $10^6$  times more basic than that of the analogous Me complex; this is presumably due to the electronically saturated configuration of the Ni- $\eta^3$ -allyl species (18 electron). Interestingly, however, the much less basic Ni center in the Ni-Me complex is protonated first to give the (formally) Ni(IV) dication  $[(\text{triphos})Ni(H)Me]^{2+}$ , whereas the precise site of attack for the Ni- $\eta^3$ -allyl complex could not be determined because of the relatively small difference (ca. 30 times) between the basicities of the metal/ligand sites.

### 3.4 Alkenyl Complexes

The reactions of alkynes or alkenes with Ni-R bonds are important in organic synthesis, particularly when they involve metallacyclic precursors because these reactions lead to synthetically valuable poly- or heterocyclic derivatives. A crucial question in this context is the regioselectivity of the insertion reaction. To address this issue, a systematic study has been carried out on the insertion of various unsymmetrical alkynes into the Ni-C(sp<sup>2</sup>) bond of the nickellacycle (8) (Scheme 14); structural analysis of the fairly stable 7-membered ring Ni-alkenyl products (9) indicates that the insertions are primarily governed by electronic factors.<sup>42</sup>

### 3.5 Silyl Complexes

Transition metal-catalyzed transformations of organosilicon compounds continue to make important contributions to organic synthesis and hold great promise for developing efficient routes to Si-based functional materials. The need to understand the mechanisms of these transformations and develop new methodologies has inspired researchers to probe the fundamental reactivities of silanes with a variety of transition metal complexes. The reactivities of Ni complexes with hydrosilanes have been studied quite vigorously and a number of interesting transformations have been reported recently, some of which are described below.

Scheme 14

The reaction of  $Ni(dmpe)_2$  ( $dmpe$  = bis(dimethylphosphino)ethane) with 1,2-disilylbenzene (10) has formed a number of interesting bis(silyl) species (11–13) that seem to be intermediates leading to the rare tetrasilyl Ni(IV) complex (14) and the (apparently) Ni(III)-Ni(III) dimer bearing  $\mu$ -silylene moieties (15), as shown in Scheme 15.<sup>43,44</sup>

Solid-state structure determinations carried out on (13–15) have provided useful data for Ni-SiR<sub>3</sub> bond lengths. For instance, the longer Ni-Si bonds for the mutually *trans* silyl moieties in (14) compared to those of the silyl ligands *trans* from the phosphine ligands (2.29 Å vs. 2.25 Å) confirms the very strong *trans* influence of silyl ligands. On the other hand, the Ni-Si distances in (15) are fairly long (2.21–2.30 Å) even though they are not *trans* from one another; in addition, the Ni-Ni distance (ca. 2.70 Å) is longer than a usual Ni-Ni single bond, while the adjacent Si-Si distances are short enough for a weak bonding interaction (ca. 2.69 Å). The latter observations might imply that complex (15) can be viewed alternatively as a Ni(I)-Ni(I) species bearing two  $\mu$ -silyl moieties formed by the dimerization of (10) (dehydrogenative formation of two Si-Si bonds), as shown in Scheme 16.

The validity of this alternative view is supported by the finding that reacting Ni(0) species with (16), the dimethyl analogue of (10), allowed the isolation of a new product (17) containing an 8-membered cyclic disilyl ligand that has formed by the dimerization of (16) (Scheme 17). The Si-Si bonds in this species (ca. 2.36 Å) were shorter than the analogous distances in (15).

## 4 Ni(0) COMPLEXES

Organometallic complexes of Ni(0) display a rich array of reactivity both in stoichiometric reactions (e.g. oxidative additions (see *Oxidative Addition*), cycloadditions, etc.)

Scheme 15

Scheme 16

Scheme 17

and in catalysis (e.g. cross-coupling reactions). Curiously, however, a relatively small number of  $\text{Ni}(0)$  complexes have found practical utility as versatile precatalysts or stoichiometric reagents in organic transformations (e.g.  $\text{Ni}(\text{PR}_3)_n$ ,  $\text{Ni}(\text{PR}_3)_n(\text{CH}_2=\text{CH}_2)_m$ ,  $\text{Ni}(\text{COD})_2$ ,  $\text{Ni}(\text{bipy})_2$ , etc.), while the reactivities of most complexes of zerovalent

nickel remains unexplored. A significant development in this context has been the introduction of  $\text{Ni}(0)$  complexes bearing N-heterocyclic carbenes (*see Carbene Complexes*),<sup>45</sup> which have spearheaded a renewal of interest in the catalytic chemistry of  $\text{Ni}(0)$  in many different directions. Some of these developments are described below, followed by an

overview of the reactivities of a number of other Ni(0) species introduced recently.

#### 4.1 N-heterocyclic Carbene Complexes

N-heterocyclic carbenes have been used extensively over the past decade as versatile alternatives to the ubiquitous tertiary phosphines. These ligands are strongly electron donor, weakly  $\pi$ -acceptor, and in most cases quite bulky.<sup>46–48</sup> The stoichiometric reactions of Ni-carbene complexes are quite similar to those of analogous phosphine complexes; for example, oxidative addition of aryl- or alkyl-halides gives square planar bis(carbene)Ni(R)X species.<sup>49</sup> On the other hand, a number of side-reactions have been observed for the carbene complexes, such as the addition of electrophiles like alkyl halides to the carbene ligand instead of the metal center; it is believed that the imidazolium salts produced in this reaction form as a result of the elimination of the hydrocarbyl (see *Hydrocarbonyl*) and carbene ligands. This is an important reactivity since many catalytic reactions are believed to go through such square planar Ni(II) intermediates bearing hydrocarbyl moieties; hence, side-reactions such as this might undermine the potential of carbenes in catalysis. Nevertheless, an increasing number of important reactions have already been catalyzed efficiently by Ni-carbene precursors. For instance, it has been shown that the cross-coupling of aryl bromides with phenylboronic acids (the Ni-analogue of the well-known Suzuki coupling) is catalyzed by (carbene)<sub>2</sub>Ni(Ar)Br with a catalytic turnover of ca. 2000.<sup>50</sup>

A series of Ni(0)-carbenes have been studied in order to determine the level of electron-donation of heterocarbenes as well as the Ni-carbene bond dissociation energies. Thus, the  $\nu(\text{CO})$  values for (carbene)Ni(CO)<sub>3</sub> were used to show that the heterocarbene ligands bearing N-mesityl substituents are at least as donating as P(*t*-Bu)<sub>3</sub>; on the other hand, the carbenes bearing N-adamantyl and N-*t*-Bu substituents appear to form relatively labile C–Ni bonds (BDE = ca. 40 kcal mol<sup>–1</sup>) in (carbene)Ni(CO)<sub>2</sub>.<sup>51</sup> These findings should prove important in interpreting the catalytic reactivities of Ni-carbene complexes.

Ni(0)-carbene complexes (see **Carbene Complexes**) can be prepared in situ by mixing a Ni(0) precursor with the desired carbene ligand (Scheme 18). This protocol can be further simplified by the in situ generation of both the Ni(0) species and the carbene ligand from readily available starting materials, as shown below; the distinct <sup>13</sup>C NMR

signal for the carbene carbon (ca. 220 ppm) can be used to monitor the formation of the target complex.<sup>52</sup>

Ni(carbene)<sub>n</sub> species generated in situ have been used to effect the catalytic coupling of dienes and variously substituted benzaldehydes in the presence of HSiEt<sub>3</sub> to give the Z-homoallylic silyl ethers (**18**) in 5–20 catalytic turnovers (equation 4);<sup>53</sup> it is interesting to note that using PPh<sub>3</sub> analogues of the Ni(0) complexes (*n* = 2) gives the E-isomer.<sup>54</sup>

Ni(0) carbenes are also effective for the Kumada–Corriu coupling reaction between arylmagnesium reagents and aryl chlorides<sup>55</sup> or fluorides<sup>56</sup> in ca. 35 catalytic turnovers (equation 5). The yields are generally high even at room temperature (ca. 30 turnovers over 18 h); only when the aryl chloride is congested (substituents ortho to Cl) does the yield suffer. It is noteworthy, however, that very similar yields were obtained when the N-heterocarbene ligands were replaced by *t*-Bu<sub>3</sub>P.

#### 4.2 Phosphorous-containing Complexes

Phosphines provide suitable coordination environments for the preparation of stable yet reactive Ni(0) species. A recently introduced member of this family of complexes contains a cyclic oligophosphine ligand and was prepared by reacting the cyclic pentaphosphanide anion (**19**), [P<sub>5</sub>(*t*-Bu)<sub>4</sub>]<sup>–</sup>, with a source of Ni(II) (Scheme 19); given the isolobal analogy between P and C–H, the resulting complex (**20**) can be viewed

Scheme 18

Scheme 19

Scheme 20

as an analogue of  $(\text{PR}_3)_2\text{Ni}(\text{cycloalkene})$ . The solid-state structure of **(20)** has been studied by X-ray crystallography, which showed that the geometry of the Ni center is distorted trigonal planar ( $\text{Et}_3\text{P}-\text{Ni}-\text{PEt}_3$  ca.  $108^\circ$ ;  $\text{P}-\text{Ni}-\text{P}$  ca.  $56^\circ$ ). The average  $(t\text{-Bu})\text{P}-\text{P}(t\text{-Bu})$  distance of  $2.20 \text{ \AA}$  is in the expected range for P–P single bonds, whereas the shorter P–P distance of  $2.12 \text{ \AA}$  implies that the P atoms bonded to Ni are multiply bonded; therefore, **(20)** can be justifiably considered a formally 16-electron Ni(0) species.

A recent report has described a series of Ni(0)-alkynylphosphine complexes **(21)** featuring the unusual coordination of the alkyne moiety in preference over the phosphine moiety (Scheme 20).<sup>57</sup> The reaction of these Ni(0)-alkyne complexes with HCl and the isolation of the resulting Ni(II)  $\eta^2$ -vinyl complexes **(22)** has provided a rare opportunity to study alkyne insertion reactions. The Ni–P bond in **(22)** undergoes another insertion (*see Insertion*) by  $\text{CO}_2$  or  $\text{CS}_2$  to give 5-coordinate, zwitterionic (*see Zwitterion*) complexes **(23)**.

Alkynylphosphines have also been shown to undergo an interesting double insertion with Ni(0)-benzyne complexes. Thus, two equivalents of  $\text{Ph}_2\text{P}-\text{CC}-\text{R}$  insert into the Ni-benzyne bond in **(24)** to form a series of novel naphthalene-based bis(phosphine) ligands coordinated to the Ni center **(25)**,

equation (6).<sup>58</sup>

### 4.3 Cyclopropene-containing Complexes

A number of Ni(0) complexes containing a cyclopropene ligand have been prepared and shown to catalyze the oxidative coupling of cyclopropene derivatives to compounds with a cyclobutane core (Scheme 21). A recent study of the kinetics of these reactions has led to the isolation

Scheme 21

of a putative intermediate (26).<sup>59</sup> Thus, the reaction of  $(bipy)Ni(COD)$  with 3-methyl-3-(*t*-Butyl)-1-cyclopropene-1,2-dimethyl dicarboxylate forms the Ni(0)-cyclopropene compound (26), which crystallizes in a trigonal planar structure. It is interesting to note that the carboxylate substituents are bent out of the coordination plane, while the *t*-Bu group is *endo* with respect to the Ni center; this orientation is presumably favored over the alternative *cis* disposition of the *t*-Bu and carboxylate substituents, which would engender greater steric (see *Steric Effect*) repulsions.

## 5 CATALYTIC POLYMERIZATION AND COPOLYMERIZATION OF OLEFINS

The study of olefin polymerization reactions catalyzed by complexes (see *Oligomerization & Polymerization by Homogeneous Catalysis*) of late transition metals experienced a significant progress during the 1990s and the rapid pace of progress continues unabated during the present decade. The driving force for the intense activity in this area is the belief that, in comparison to catalytic systems based on early metal complexes (e.g. group 4 metallocenes), systems based on the less electrophilic late transition metal complexes will allow the development of polymerization protocols that are tolerant

of olefinic monomers possessing polar functional groups. The incorporation of such units in ethylene-based copolymers is expected to furnish new macromolecules possessing novel structural properties and promising applications. On the other hand, the main obstacle for the development of efficient catalytic systems based on late metals was the well-documented propensity of late transition metal complexes in general, and Ni-based catalysts, in particular, to favor oligomerization over polymerization.<sup>60</sup> This behavior stems from the readiness with which alkyl complexes of nickel (and of most late transition metals) undergo  $\beta$ -H elimination (see  *$\beta$ -Hydride Elimination*) reactions; these reactions in effect rearrange the alkyl moiety into a (new) olefin, which is then expelled from the metal's coordination sphere, as shown in Scheme 22. The  $L_nM-H$  species generated in this sequence can then undergo an insertion reaction with another molecule of olefin to restart the oligomerization process; this olefin is usually the monomer, which is present in the reaction mixture in higher concentrations and is less bulky.

In light of the above, it is generally assumed that the key to extending the olefin homologation (see *Homologation Reactions*) process beyond dimerization or oligomerization is to retard the above-described  $\beta$ -H elimination (see  *$\beta$ -Hydride Elimination*) (or de-insertion) and chain-transfer reactions. This objective was achieved most spectacularly when it was demonstrated, in 1995, that a family of Ni(II) complexes bearing  $\alpha$ -diimine ligands (27) had unexpectedly

Scheme 22

high activities for the polymerization of ethylene.<sup>61</sup> (NB: These complexes and their Pd(II) analogues have been trademarked Versipol catalyst systems by DuPont.) This reactivity was later extended to other terminal, aliphatic olefins (propylene, 1-hexene, 1-octene, etc.).<sup>62</sup>

It is noteworthy that this family of complexes had been known for decades,<sup>63</sup> but what made the newly introduced derivatives excellent catalysts for polymerizing ethylene was the incorporation of very bulky aryl substituents (e.g. 2, 6-(*i*-Pr)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>) on the diimine nitrogens. Solid-state structural and computational studies have indicated that the aryl

substituents orient themselves approximately perpendicular to the coordination plane, thus placing the ortho substituents above and below this plane. It seems, therefore, that the role of these substituents is to provide steric crowding around the axial plane above the Ni center, which in effect blocks the interaction of the growing alkyl chain with the  $d_{z^2}$  orbital, thereby hindering the  $\beta$ -H elimination step. Other crucial features of these systems include their cationic nature and the use of noncoordinating counter anions during the ionization step; together, these factors increase the electrophilicity of the central metal and provide an open coordination site for the uptake and insertion of the monomer.

In a typical polymerization experiment, the (diimine)NiX<sub>2</sub> precursor is generated in situ and reacted with 100–1000 equivalents of methylaluminoxane (MAO, {MeAlO}<sub>n</sub>) in toluene ( $\mu\text{mol conc. in Ni}$ ) under a small pressure of ethylene (typically 1 atm) at about 35 °C (Scheme 23). Typical activities are hundreds of kg of poly(ethylene) (PE)/mol Ni.h, although they can be one or two orders of magnitude higher under optimized conditions. The molecular weights of the resulting PE can range from 3 to 1000  $\times 10^3$  Daltons, and the polymer

Scheme 23

Scheme 24

microstructure can vary from highly linear and crystalline to fairly branched and amorphous. In general, PE samples obtained with Ni catalysts are less branched in comparison to the corresponding Pd systems.

The mechanism of the polymerization reactions catalyzed by the Ni(diimine) system has been studied in detail both experimentally<sup>64</sup> and by computational methods.<sup>65–69</sup> Since a number of cationic species of the type [(diimine)Ni(n-alkyl)(olefin)]<sup>+</sup> can be observed throughout the reaction, it is believed that these intermediates are formed in relatively rapid steps (e.g. rapid monomer uptake) and consumed in relatively slow steps (e.g. the migratory insertion of the monomer into the Ni-alkyl bond). Therefore, such species represent the catalyst resting state and their reactions are considered to be rate-limiting (Scheme 24). This type of reactivity also implies that the chain growth is zero-order with respect to the concentration of ethylene, although this is not the case with higher  $\alpha$ -olefins. The barrier to the insertion reaction has been estimated (by low-temperature NMR techniques (*see Structure & Property Maps for Inorganic Solids*)) to be ca. 13–14 kcal mol<sup>-1</sup>, which is ca. 4–5 kcal mol<sup>-1</sup> lower than the barrier for the insertion step for the analogous Pd complexes. Some of the computational studies<sup>70</sup> have produced rate data that are in close agreement with these values.

As mentioned earlier, the very bulky N-substituents tend to hinder the chain-transfer or  $\beta$ -H elimination (*see  $\beta$ -Hydride Elimination*) steps; moreover, the larger steric bulk is thought to destabilize the resting state with respect to the insertion transition state. In other words, the bulky substituents favor the chain growth process by both accelerating the propagation step (insertion of the monomer) and by retarding the termination steps (the chain-transfer or  $\beta$ -H elimination steps). The formation of branched PE can be rationalized as follows: the 14-electron intermediate [(diimine)Ni(n-alkyl)]<sup>+</sup> generated by the insertion process (**28**) can either trap a monomer and undergo another insertion reaction leading to linear chain growth, or it can be stabilized by agostic C–H–Ni interactions (*see Agostic Bonding*) that can produce [(diimine)Ni(branched-alkyl)]<sup>+</sup> intermediates (**29**) via successive  $\beta$ -H elimination/reinsertion steps. The intermediate with the branched-alkyl moieties can then trap monomer and undergo insertion to give branched PE. This process is dubbed ‘chain-walking’.

Another remarkable character of this class of Ni complexes is their tendency to promote living polymerization of  $\alpha$ -olefins at low temperatures and with low concentrations of the monomer. Thus, the low-temperature polymerization of propylene leads to a material whose number average molecular weight ( $M_n$ ) increases almost linearly as a function of time and propylene consumption, reaching values of  $M_n = 160\,000$  Daltons and polydispersities of ca. 1.13.<sup>71</sup> This character allows these Ni catalysts to produce A-B-A type block copolymers composed of semicrystalline and amorphous segments, which is used to prepare thermoplastic elastomeric polymers. The Ni catalysts can also polymerize internal cyclic

olefins such as cyclopentene, giving high molecular weight materials ( $M_w \sim 250\,000$  Daltons) that are melt-processable to strong, clear films.

The relative insensitivity of this class of Ni catalysts to polar functional groups, and especially their low oxophilicity, is another important characteristic. This property has been exploited for the development of novel polymeric materials that might find new applications. For example, 1-hexene has been copolymerized with 6-(2-ureido-4-[1H]-pyrimidinone)hex-1-ene (**30**) to generate a new poly(olefin) elastomer (equation 7).<sup>72</sup> The dimerization (through H-bonding) of the pyrimidinone moieties forms noncovalent crosslinks that bestow unique properties to the otherwise amorphous poly(1-hexene) matrix.

### 5.1 Ni-based Neutral Catalysts for Olefin Polymerizations

Following the successful development of the above-discussed cationic systems, there has been a surge of interest to develop neutral, single-component systems not requiring cocatalysts such as MAO. As before, it was anticipated that the reduced electrophilicity of noncationic systems and their tolerance for polar functionalities on the olefinic monomers will further facilitate the use of olefinic monomers bearing polar groups. The Ni complexes (**31**) based on the salicylaldiminato ligand were found to be promising catalysts for this purpose,<sup>73</sup> particularly when a bulky substituent was placed *ortho* to the OAr position, because this feature allowed the catalysis to proceed without the customarily required

initiators/cocatalysts.<sup>74</sup> Evidence from experimental studies indicates that the main role of the bulky Ar-substituent is to induce the dissociation of the PPh<sub>3</sub> ligand, thereby opening up a coordination site around the Ni center; computational studies are in accord with this proposal.<sup>75</sup>

Ar = 2,6-(iPr)<sub>2</sub>C<sub>6</sub>H<sub>3</sub>

R = H, Ph, *t*-Bu, 9-phenathrenyl, 9-anthracenyl

In addition to ethylene, the precatalysts (31) homo- and copolymerize styrene and norbornene and copolymerize ethylene with  $\alpha$ -olefins (e.g. 1-hexene, 1-octene, etc.) or functionalized norbornenes (e.g. 5-norbornene-2-ol). Remarkably, the polymerization of ethylene can proceed in the presence of various polar molecules such as ethers, ketones, esters, amines, alcohols, and even water! This tolerance of extremely polar media has been exploited to carry out Ni-catalyzed polymerization of ethylene in aqueous emulsions.<sup>76–78</sup> This type of polymerization protocol leads to so-called polymer latexes, which consist of stable aqueous dispersions of surfactant-stabilized microparticles of the polymer having diameters in the range of tens or hundreds of nm. In addition to the obvious advantage of using aqueous media for polymer synthesis, the polymer latexes produced by emulsion polymerizations have also many varied applications (e.g. in coatings). In a particularly attractive approach to applying emulsion polymerization protocols to metal-catalyzed reactions, hydrocarbon solutions of the Ni-based system (32) were dispersed in water/surfactant mixtures and exposed to ethylene pressure; this led to PE latexes consisting of long chains ( $M_w$  ca.  $10^5$  Daltons) and having average particle sizes of 50–350 nm in diameter.<sup>79</sup>

Recent reports have described other neutral, single-component Ni catalysts based on the N–O ligands

2-anilinothione (33)<sup>80</sup> and 2-anilinothione (34).<sup>81</sup> There are a number of structural similarities between these and the above-described salicylaldiminato-based systems in that they all incorporate N–O ligands in addition to PPh<sub>3</sub> and Ph ligands (Ph *trans* to O, PPh<sub>3</sub> *trans* to N). On the other hand, there are also important differences such as (a) the greater localization of the negative charge on the N-atom in the new systems as opposed to on the O atom in the salicylaldiminato system, and (b) the formation of a 5- as opposed to 6-membered chelate metallacycles (see *Metallacycle*). The latter feature results in different bite angles: O–Ni–N angles of ca. 83° vs. ca. 94° and O–Ni–P angles of ca. 95° vs. ca. 87° for the 2-anilinothione (33) and salicylaldiminato (34) systems, respectively. The activities of the new complexes are up to ca. 60 000 kg PE/h.mol of Ni, which is comparable to, or higher than, those of the best salicylaldiminato systems, but their lifetimes are shorter. The thione system (33) has the interesting property of tolerating many functional groups (ether, THF, water, NEt<sub>3</sub>, etc.) in addition to being fairly insensitive to the presence of added PPh<sub>3</sub> ligand; thus, even the presence of 5 equivalents of PPh<sub>3</sub> has essentially no effect on the activities.

Although most of the Ni-based catalyst systems displaying high activities in the polymerization of ethylene bear N-based ligands, there have been a few reports on the catalytic reactivities of P-based Ni complexes. Recall that the nickel indenyl complexes IndNi(PR<sub>3</sub>)<sub>3</sub>X discussed earlier polymerize ethylene to high MW PE with activities ranging from 50 to 700 kg PE/mol of Ni.h ( $P_{\text{ethylene}} = 5\text{--}10$  atm).<sup>16</sup> Higher activities up to 2000 kg PE/mol of Ni.h ( $P_{\text{ethylene}} = 8$  atm) have been obtained from LNiBr<sub>2</sub> (35) with L representing the chelating bis(phosphine) MeN{P(2-*i*-Pr-C<sub>6</sub>H<sub>4</sub>)<sub>2</sub>}<sub>2</sub>.<sup>82</sup> Both of these systems require cocatalysts/activators such as MAO, and in both cases it has been shown that the presence of AlMe<sub>3</sub> in the reaction mixture lowers polymerization activities. Like the other Ni-based systems described above, these catalysts are fairly insensitive to polar functional moieties present in the polymerization medium.

As discussed earlier, the electronically and coordinatively unsaturated cations [IndNi(PR<sub>3</sub>)<sub>3</sub>]<sup>+</sup>, which are generated from the corresponding Ni–X precursors in the presence of excess MAO or other halide abstractors such as AgBF<sub>4</sub>, promote exclusively the dimerization of ethylene. The 1-butene

produced during the polymerization reaction is incorporated into the PE chains, leading to ca. 5% ethyl branches along the essentially linear PE produced by this system. The PE obtained from the bis(phosphine) system is also essentially linear but contains a small number of different branches (mostly Me branches but longer homologues are also detected), indicative of the chain-walking mechanism.

## 5.2 Alternating Copolymerization of CO and Ethylene

The alternating copolymerization of CO and ethylene has been studied in much detail over the past two decades.<sup>83</sup> Although a number of Ni-based systems are known to catalyze this reaction,<sup>84,85</sup> comparative studies have shown that Pd-based systems are by far the most active catalysts for this reaction. The lower activity of the Ni-based systems is somewhat surprising because the requisite CO and ethylene insertion steps are expected to be energetically more facile for the Ni-based systems. A recent study has shown that the energy barrier for CO insertion into the Ni–Me bond is less than 10 kcal mol<sup>−1</sup> (Scheme 25),<sup>86</sup> significantly lower

than the barrier of ca. 15 kcal mol<sup>−1</sup> in the analogous Pd complexes; this finding supports the results of computational studies that predict barriers on the order of 4–7 kcal mol<sup>−1</sup> for simplified Ni systems.<sup>87</sup> The reaction of the Ni-acyl complex (37), which is formed from the initial CO insertion into the Ni–Me bond in (36), with ethylene gives a new Ni-acyl species (38) instead of the expected Ni-alkyl intermediate; this is presumably caused by the very facile insertion of CO into the Ni-alkyl bond arising from the ethylene insertion. Since the CO insertion is reversible, argon-purging of the reaction solution for an extended period produces a new Ni-alkyl species bearing a pendant, chelating acyl moiety (39). It appears, therefore, that the facile uptake and insertion of CO stabilizes the catalyst resting state in the Ni-based systems, making these systems less efficient catalysts relative to the Pd-based systems. Moreover, the Ni-catalyzed copolymerization reaction seems to involve stable, 5-coordinate intermediates, in contrast to the almost exclusive involvement of 4-coordinate species in the Pd-based systems.

## 6 OTHER CATALYTIC REACTIONS

### 6.1 Ni-catalyzed Cross-coupling Reactions

The Ni-catalyzed cross-coupling of organic halides with various other organometallic reagents (e.g. RLi, RMgX, XZnR, etc.) plays an important role in organic synthesis. A number of recent reports have introduced important developments in this area, which promise to improve the potential of Ni-catalyzed routes for making new C–C bonds. For example, it was shown in 1998 that diorganozinc (*see Zinc: Organometallic Chemistry*) reagents can be coupled with alkyl halides (Negishi reaction) if a suitable  $\pi$ -donor

Scheme 25

ligand was used to induce the reductive elimination of the product from the postulated diorganonickel intermediates (equation 8).<sup>88</sup> This protocol has been revised more recently to extend the coupling reaction to  $RZnI$ , which are less reactive than  $ZnR_2$  but also more tolerant of functional groups; thus, ethers, esters, ketones, amides, and nitriles can be tolerated.<sup>89</sup> The presence of  $Bu_4NI$  is essential for this protocol; the role of this additive is not clear, but it might coordinate to  $RZnI$  to form a more nucleophilic organozinc anion.

The cross-coupling of more hindered secondary and tertiary alkyl halides has also been studied. Thus, secondary alkyl halides can be cross-coupled with organozinc reagents in the presence of the so-called 'pybox' ligands (equation 9).

An interesting development concerning the mechanistic aspects of the Negishi cross-coupling reaction was the recent report that  $ZnBr_2$  can abstract a bromide atom from  $L_2Ni(R)Br$ , generating  $[L_2NiR]^+$  cations (Scheme 26). Since both  $ZnX_2$  and organyl halides of nickel are proposed intermediates in the Negishi reaction, this finding is likely to have important consequences for the future developments in this area.

In another development, it was shown that simple  $Ni(II)$  or  $Ni(0)$  precursors (e.g.  $NiCl_2$ ,  $Ni(acac)_2$ ,  $Ni(COD)_2$ , etc.) can catalyze the coupling of primary alkyl halides with Grignard reagents (Kumada–Corriu reaction).<sup>90</sup> This otherwise challenging coupling of two  $sp^3$ -C centers is facilitated by the presence of various 1,3-butadienes; this feature allows even the normally unreactive alkyl chlorides to be coupled in very good yields and low catalyst loadings

(equation 10). The precise mechanism of this reaction is not known, but free radical-based routes have been excluded; a tentative proposal has invoked the involvement of  $Ni(IV)$  intermediates.

## 6.2 Ni-catalyzed Coupling of Carbonyl Compounds with Alkynes or 1,3-dienes

A number of new Ni-catalyzed protocols have been developed recently for the coupling of carbonyl compounds and unsaturated substrates such as alkynes or 1,3-dienes.<sup>91–94</sup> For instance, a three-component intramolecular coupling (alkyne/aldehyde/hydrosilane) has led to the formation of bicyclic N-heterocycles. A number of similar inter- and intramolecular coupling reactions have been developed into useful synthetic routes (Scheme 27).

## 6.3 Ni-catalyzed $CO_2$ Additions

A novel Ni-promoted route has been developed for using  $CO_2$  as a natural source of acid/ester moieties in building organic molecules. This reaction, which provides an attractive method for preparing a number of mono- and di-carboxylic acid derivatives, proceeds by the oxidative cycloaddition of  $CO_2$  to conjugated dienes as exemplified in the transformations shown in Scheme 28.<sup>95</sup> The reaction of  $Ni(COD)_2$  (in stoichiometric amounts) with the diene and  $CO_2$  (1 atm) is believed to produce the oxo- $\pi$ -allyl nickel intermediates (**40**) that can be hydrolyzed or transmetalated (*see Transmetalation*) with zinc reagents; the presence of two equivalents of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) is essential for the success of the transformation. It is not known why  $ZnMe_2$  leads to dicarboxylation whereas  $ZnAr_2$  gives arylative carboxylation.

## Abbreviations

$\beta$ -dikH =  $\beta$ -diketone; silox = OSi $t$ Bu<sub>3</sub>; thdH = 2,2,6,6-tetramethylheptane-3,5-dione; THT = tetrahydrothiophene, Tp\* = hydridotris(3,5-dimethylpyrazolyl)borate, Tp = hydridotris(pyrazolyl)borate, R<sub>2</sub>-dad = *N,N'*-substituted 1,4-diaza-1,3-diene, R<sub>2</sub>pz = alkyl-substituted pyrazolato, salophen = *N,N'*-*o*-phenylenebis(salicyldeneaminato) dianion.

## 1 INTRODUCTION: SURVEY AND GENERAL TRENDS

Niobium (formerly called columbium) and tantalum are *Transition Metals* having a considerable affinity for oxygen donor groups; they are thus called oxophilic (see *Oxophilic Character*). They occur as mixed-metal oxides such as columbites (Fe/Mn)(Nb/Ta)<sub>2</sub>O<sub>6</sub> and pyrochlore NaCaNb<sub>2</sub>O<sub>6</sub>F. Their discovery in minerals extends back to the beginning of the nineteenth century, when they were believed to be identical and called tantalum. Rose showed that at least two different elements were involved in the minerals, and named the second one niobium. Their separation was resolved around 1866, especially by Marignac. These metals often display similar chemical behavior as a result of nearly identical atomic radii (1.47 Å) due to the lanthanide contraction (see *Periodic Table: Trends in the Properties of the Elements*)

and of similar ionization energies (see *Ionization Potential*); (Nb 6.67 eV, Ta 7.3 eV). Their separation is, nevertheless, possible and was long based on the greater tendency of tantalum to form insoluble anionic MF<sub>7</sub><sup>2-</sup> complexes. Their modern separation uses liquid–liquid extraction into isobutyl methyl ketone from hydrofluoric acid.<sup>1</sup>

The chemistry of niobium and tantalum ranges from oxidation states +V to –III. No species of oxidation state –II is known so far (Table 1) and the chemistry is dominated by the higher oxidation states, especially V. By contrast with the 3d transition metals, the [M(H<sub>2</sub>O)<sub>6</sub>]<sup>*n*+</sup> ions are unknown and the aqueous chemistry of the higher valence states is dominated by the formation of homo- and heteroisopolyanions (see *Polyoxometalates*). They have an extensive lower oxidation state aqueous chemistry based on hexanuclear clusters. Most recent developments have been in their nonaqueous chemistry in intermediate oxidation states since these species are able to promote C–E (E = O, S, N) cleavage and N<sub>2</sub> activation reactions. Niobium is more prone to reduction than tantalum. In their higher oxidation states, niobium and tantalum tend to resemble titanium and zirconium (see *Titanium: Organometallic Chemistry* and *Zirconium & Hafnium: Inorganic & Coordination Chemistry*) rather than vanadium, but in their lower states they are closer to molybdenum and tungsten (see *Molybdenum: Inorganic & Coordination Chemistry* and *Tungsten: Inorganic & Coordination Chemistry*). This is illustrated by their tendency to give multiple bonds with nonmetals such as oxygen, sulfur, nitrogen, or carbon (for the last see *Niobium & Tantalum: Organometallic Chemistry*) and to form hexanuclear clusters. Niobium and tantalum are among the largest early transition metals; they can easily accommodate a large number of ligands and display large coordination numbers (see *Coordination Chemistry: History*).<sup>1</sup> Hexacoordination and heptacoordination are the most common, but higher coordination numbers such as eight or even nine and ten have been observed; as a result, their derivatives often have a dynamic coordination sphere and are fluxional (see *Fluxional Molecule* and *Stereolability*).<sup>1,2</sup>

Niobium finds use in the production of stainless steels for high temperatures, and in superconducting magnets. The high corrosion resistance of tantalum results in its use for chemical plants. The binary and ternary oxides of these elements arouse increasing interest as electronic ceramics. Their full potential as reagents in organic synthesis lies in the development of their lower oxidation state chemistry as compared to other oxophilic early transition metals. Niobium pentoxide has been used in heterogeneous *Catalysis* either as catalyst or as support (see *Oxygen: Inorganic Chemistry*).

Both metals are active in NMR (spin 9/2 for <sup>93</sup>Nb, 7/2 for <sup>181</sup>Ta) and have high sensitivities, but their major drawbacks are their large quadrupole moments that often result in broad signals (several kHz) in low symmetry environments, and thus application of NMR remains limited, especially for tantalum. <sup>181</sup>Ta is a nucleus with interesting characteristics

**Table 1** Oxidation states and common stereochemistries of Nb and Ta compounds

| Oxidation state   | Coordination number | Idealized geometry        | Examples                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

for *Mössbauer Spectroscopy* and this technique has been applied for the study of sulfide intercalation compounds.<sup>2</sup>

## 2 OXIDATION STATE V

### 2.1 Halogens as Ligands: Pentahalides and their Anionic and Neutral Adducts

Niobium and tantalum pentahalides  $\text{MX}_5$  are known for all halogens including iodine.<sup>1</sup> They are predominantly covalent (see *Covalent Bonds*), and all are sensitive to moist air, water, or hydrolytic solvents. Pentahalides, especially chlorides, provide the most convenient entry to the molecular chemistry of these elements. They are commercially available and can be prepared by reactions between metals, oxides, or halides and the appropriate halogenation reagent at high temperatures.  $\text{NbI}_5$  is the less stable pentahalide (dissociation at 200 °C) and must be prepared and sublimed in the presence of excess iodine. In the solid state, the metals are hexacoordinate; this is achieved by association of  $\text{MX}_5$  units as tetramers for  $\text{MF}_5$ , as discrete dimers for  $\text{MCl}_5$  and  $\text{MBr}_5$ , and as layers of dimers for  $\text{TaI}_5$  and  $\beta\text{-NbBr}_5$ . The dimers can be viewed as two octahedra sharing an edge (Figure 1). In the vapor phase, dissociation into monomers occurs for the dimers, while the pentafluorides exist as a mixture of monomers, dimers, and trimers.

$\text{MF}_5$  and  $\text{MCl}_5$  are strongly electrophilic (see *Electrophile and Electrophilic Reaction*) and catalyze Friedel–Crafts reactions. The  $\text{HF}/\text{TaF}_5$  system is a superacid catalyst and has been used in the selective acid-catalyzed isomerization and hydrogenolysis of cycloalkanes. Oligomerization and polymerization of alkynes with  $\text{Nb}^{\text{V}}$  and  $\text{Ta}^{\text{V}}$  halides as catalysts have been reported (see *Oligomerization & Polymerization by Homogeneous Catalysis*).<sup>1</sup>

Pentahalides form adducts with nearly all types of neutral or anionic donors.<sup>1–5</sup> The high Lewis acidity of  $\text{MF}_5$  is illustrated by facile fluoride transfer and formation of anionic adducts. Species such as  $\text{MF}_{5+n}^{n-}$  ( $n = 1–4$ ) and  $\text{M}_2\text{F}_{11}^-$  have been detected in HF solutions of the metals using a selective fluoride ion electrode or by  $^{19}\text{F}$  NMR. These complexes

can be extracted by organic solvents. Niobium and tantalum pentafluorides form double salts (see *Double Salt*) with most ionic fluorides (see *Ionic Bonds*) by mixing of the constituents in the molten state, or by addition of a fluoride to the oxides in aqueous HF. The fused salt baths used in the electrolytic production of the metals contain mainly the  $\text{MF}_7^{2-}$  and  $\text{MF}_8^{3-}$  anions, whose structure has been solved by X-ray diffraction (see *Diffraction Methods in Inorganic Chemistry*).  $\text{MF}_7^{2-}$  display luminescence properties (see *Luminescence*). Mixed-metal fluoroanions and mono- or dioxofluoro complexes are known.<sup>1–5</sup> Facile corrosion of borosilicate glass by  $\text{Cp}_2^*\text{TaF}_3$  giving a ionic tetrafluoroborate complex has been observed.<sup>6</sup>

The higher halides  $\text{MCl}_5$  and  $\text{MBr}_5$  show much less affinity for  $\text{Cl}^-$  and  $\text{Br}^-$  than does  $\text{MF}_5$  for  $\text{F}^-$ . Halogen transfer reactions are nevertheless observed, mostly when these  $\text{MX}_5$  halides are allowed to react with  $\text{AX}$  ( $\text{A}^+ =$  alkali metals,  $\text{NH}_4$ ,  $\text{NR}_4$ ,  $\text{PPh}_4$ ,  $\text{AsPh}_4$ ), thus giving  $\text{A}^+\text{MX}_6^-$ . The octahedral symmetry of the  $\text{MX}_6^-$  anions is favorable for obtaining sharp  $^{93}\text{Nb}$  or  $^{181}\text{Ta}$  NMR lines and explains their use as NMR references for these nuclei. Mixed-halide anions have been recognized by  $^{93}\text{Nb}$  NMR on mixtures of  $\text{NbCl}_5$  and  $\text{NbBr}_5$  in acetonitrile.

The pentahalides form coordination compounds  $\text{MX}_5\text{L}_n$  ( $n = 1$  or 2, generally) with a large variety of Lewis bases L. The monoadducts  $\text{MX}_5\text{L}$  are octahedral, monomeric, and generally nonelectrolytes. Stability constants have been determined by proton NMR (see *Stability Constants & their Determination*). Bis adducts  $\text{MX}_5\text{L}_2$  have also been isolated for many oxygen, sulfur, nitrogen, and phosphorus donors. The  $\text{MF}_5\text{L}_2$  adducts are mostly ionic in solution, while molecular seven-coordinate species appear to be equally likely in the solid. IR data have shown greater acceptor capacity for  $\text{NbF}_5$  than for  $\text{TaF}_5$  toward the phosphoryl ligands.<sup>3</sup> Analogous chloride and bromide complexes are essentially molecular.

The pentahalides form mono or bis adducts with O-donors such as aliphatic or crown ethers, phosphine or arsine oxides, ketones, dialkyl esters, and amides. These reactions have mostly been investigated with  $\text{MCl}_5$ . Abstraction of oxygen from the ligands giving oxotrihalide adducts,  $\text{MOCl}_3\text{L}_2$ , can be promoted by heating (for ethers), by an appropriate solvent, or by an excess of ligand as for ketones or phosphine oxides (equation 1). The formation of oxychlorides appears more favorable in the case of niobium.

**Figure 1** Association of octahedra: molecular structure of the dimeric pentahalides  $\text{M}_2(\mu\text{-X})_2\text{X}_8$  ( $\text{X} = \text{Cl, Br, I}$ )

Pentahalides form essentially 1:1 adducts with sulfur, selenium, and tellurium donors, including phosphine sulfides and selenides. IR, Raman (see *Raman Spectroscopy*), and NMR studies of the complexes formed with mixed-donor O,S ligands showed bonding to occur via sulfur exclusively.<sup>1</sup> The ionic  $[\text{NbCl}_4(\eta^2\text{-S}_2\text{R}_2)][\text{NbCl}_6]$  complexes are volatile and act as a single-source precursor to mixed- $\text{Nb}_2\text{O}_5/\text{NbS}_2$  films

using *Metal–Organic Chemical Vapor Deposition* (MOCVD; see **Tin: Inorganic Chemistry**) techniques.<sup>7</sup>

Niobium and tantalum halides also form adducts with numerous N-donors. Their reactions with pyridine and related ligands (bipyridine, phenanthroline, 7-azaindole<sup>3</sup>) depend critically on the reaction conditions. Indeed, aromatic amines have a tendency to reduce the metal to oxidation state IV especially for niobium but the reduction can be prevented, even at rt, by an appropriate choice of the solvent (equations 2a–c). Imide adducts  $M(NR)Cl_3L_2$  are obtained with primary or secondary amines.<sup>8</sup>

Complexes with P- or As-donors are obtained in nonpolar media. The tendency toward increasing coordination numbers follows the decrease in the ligand's *Cone Angle* (see **P-donor Ligands**).  $NbCl_5$  forms adducts with  $\beta\text{-P}_4\text{S}_4$  and  $\text{P}_4\text{Se}_3$ , coordination occurs via the phosphorus atom.<sup>3</sup> Complexes such as  $\text{TaBr}_5(\text{diars})$  have been reformulated as ionic  $[\text{TaBr}_4(\text{diars})_2][\text{TaBr}_6]$  species.

## 2.2 Oxygen Donors

Anionic oxygen donors include ligands derived from dioxygen, that is, oxo ( $\text{O}^{2-}$ ) and peroxy ( $\text{O}_2^{2-}$ ) groups (see **Dioxygen & Related Ligands**), alkoxides, and potential chelating ligands such as  $\beta$ -diketonates, carboxylates, or oxyanions of inorganic acids.

### 2.2.1 Compounds Containing the Oxo Ligand: Oxyhalides and Derivatives

Oxyhalides such as  $\text{MOX}_3$  ( $X = \text{F, Cl, Br, I}$ ) or  $\text{MO}_2\text{X}$  may be prepared by halogenation of the oxides or controlled reaction of the pentahalides with dioxygen.  $\text{NbOCl}_3$ , the most studied, is a *Polymer* in the solid state as characterized by a strong, broad IR band at  $770\text{ cm}^{-1}$  attributed to  $\text{Nb–O–Nb}$  stretching. A band at  $997\text{ cm}^{-1}$  in the Raman spectrum of gaseous  $\text{NbOCl}_3$  is attributed to a terminal  $\text{Nb=O}$ , consistent with a monomeric *Square Pyramidal* geometry.<sup>1</sup> As a result of the oxophilic character of Nb and Ta, incorporation of oxygen into the coordination sphere is frequent. Its origin can result from adventitious water or oxygen or from oxo abstraction reactions involving the solvent or a ligand. Most of the compounds that can be formally considered as resulting from substitution of  $\text{MOX}_3$  thus derive from more complex reactions involving precursors without metal oxo bonds.

A variety of anionic oxohalo complexes has been reported. Oxofluoro complexes are formed more readily for Nb than for Ta, this difference is the basis of the classical method of separation of the two metals.  $\text{K}_2\text{TaF}_7$  precipitates before  $\text{K}_2\text{NbOF}_5 \cdot \text{H}_2\text{O}$  during the concentration of the oxides in aqueous HF. Oxo anions of the higher halides include mainly  $[\text{MOX}_5]^{2-}$  ( $X = \text{Cl, Br}$ ),  $[\text{MOCl}_4]^-$ ,  $[\text{MO}_2\text{Cl}_2]^-$ . The oxo ligand can adopt a variety of coordination modes. Dinuclear anions such as  $[\text{Ta}_2\text{Cl}_{10}\text{O}]^{2-}$  and  $[\text{M}_2\text{Cl}_9\text{O}]^-$  with nearly linear  $\text{M–O–M}$  bridges have been obtained, mostly by adventitious hydrolysis.<sup>1–5</sup> The latter is characterized by an asymmetrical  $\text{M} \cdots \text{O–M}$  bond (1.76 and  $2.08\text{ \AA}$ ) and can be seen as a complex between  $\text{NbOCl}_4^-$  and  $\text{NbCl}_5$ .<sup>7</sup> A tetranuclear niobium–alkyne anion was shown to encapsulate a  $\mu_4\text{-O}$  oxo ligand with an uncommon planar *Stereochemistry*.<sup>2</sup>

Numerous 1:1, 1:2, and 1:3 neutral adducts are known for  $\text{NbOCl}_3$ . While complexes with N-donors such as amines, nitriles, or with phosphines derive mostly from direct reaction between oxyhalides and the ligands, many  $\text{MOX}_3\text{L}_2$  complexes have been obtained by oxygen abstraction from O-donors by pentahalides. This reactivity can be exploited for an easy entry into oxychloride chemistry via the *Labile*  $\text{NbOCl}_3(\text{MeCN})_2$  complex (**1**) (equation 3).<sup>1,2</sup>

Tetranuclear monoadducts with asymmetrical  $\text{M} \cdots \text{O–M}$  bridges related to those of  $[\text{M}_2\text{OCl}_9]^-$  have been characterized; but most structural data concern monomeric  $\text{NbOCl}_3$  bis adducts. In such derivatives, the metal is octahedrally surrounded with the neutral ligands cis to each other, one being trans to the oxo bond, which is short (typical  $\text{Nb=O}$  *Bond Length*  $\sim 1.70\text{ \AA}$ ). The coordination polyhedron is distorted as a result of the niobium–oxygen multiple bond (see *Valence Shell Electron Pair Repulsion Model*).<sup>1</sup>

The stabilizing effects of the bulky and strong electron donor pentamethylcyclopentadienyl ligand  $\text{Cp}^*$  permitted investigation of the stepwise hydrolysis, in the solid state as well as in solution, of  $\text{Cp}^*\text{MCl}_4$ . The oxide ligand can be progressively introduced via hydrates or hydroxo derivatives, giving structurally characterized dinuclear or trinuclear aggregates.<sup>9</sup> These bulky ligands were also able to stabilize the simultaneous presence of oxo and hydride ligands on tantalum. Nonhalide oxo derivatives can be stabilized as monomers with bulky O- or N-donor ligands such as tri-*t*-butylsiloxide (silox), bistrimethylsilylamide, tropolone,<sup>1,2</sup> or as tetramers with trispyrazolylborate ligands.<sup>10</sup>

In aqueous solutions, numerous orthometallates ( $\text{MO}_4^{3-}$ ), metatallates ( $\text{MO}_3^{3-}$ ), and polyoxometallates, especially  $[\text{Nb}_6\text{O}_{19}]^{8-}$ , are known (see **Polyoxometallates**). Peroxo derivatives are other species obtained from aqueous solutions. Orthoperoxometallates precipitate from alkaline solutions of

**Figure 2** Coordination polyhedron of the  $M_2(\mu-O)_3(porp)_2$  dimers

niobates or tantalates on addition of  $H_2O_2$ .<sup>1</sup> In the  $Nb(\eta^2-O_2)_4^{3-}$  ion, all peroxide groups are linked side-on to the metal (see *Side-on Coordination*). Perhydrolysis of alkoxides in the presence of organic bases provides a clean route to peroxo anions. The peroxometallates release  $O_2$  progressively in mild conditions, and explosively at  $80^\circ C$ . They are converted into orthoperoxo acids by  $H_2SO_4$ . The yellow color that is developed for niobium has been used in colorimetric titration. Displacement of the peroxo ligands with chelating O- or N-donors (see *Chelating Ligands*) gives di- and triperoxo complexes. For the bisperoxo compounds, the coordination polyhedron corresponds to a distorted dodecahedron (see *Dodecahedral*), the two peroxo groups displaying an unusual cis geometry. Peroxo complexes with N-oxide derivatives of polycarboxylic acids,  $[Nb(\eta^2-O_2)_2(LO_2)]^{3-}$  ( $L = edta$ ) or pdta (propylenediaminetetracetate) have been reported.<sup>11</sup> Anionic and neutral peroxohalo derivatives, mainly peroxofluoro ones, are known; their structure has been investigated by X-ray diffraction as well as by  $^{19}F$  NMR. A cyclopentadienyl monoperoxide catalyzes the conversion of cyclohexene into its epoxide in the presence of  $H_2O_2$ .<sup>1</sup>

Most *Porphyrin* complexes are niobium oxo derivatives such as  $NbOZ(porp)$  ( $Z = F, OAc, acac$ ). Tantalum porphyrin derivatives are scarcer. The hydrolysis of  $M(porp)Cl_3$  afforded oxo dimers,  $M_2(porp)(\mu-O)_3$  (**2**) of an unusual structure since two  $M(porp)$  units are linked together through three oxo bridges (Figure 2). Structure determinations by X ray have shown that the metal lies always above the plane of the porphyrin ring and that the axial ligands have a cis geometry with respect to the ring. The redox chemistry of the Nb oxo dimer (**2**) was investigated by chemical and electrochemical means (see *Electrochemistry: Applications in Inorganic Chemistry*). The photochemically reduced Nb porphyrin derived from (**2**) is able to reduce  $O_2$  and to achieve the catalytic and exclusive epoxidation of alkenes, without additional reactant;<sup>9,12</sup> it is the first example of such an activation (see *Oxygen: Inorganic Chemistry*). Attempts to get  $Ta(OEP)Cl_3$  from  $TaCl_5$  lead to  $[Ta(OEP)_2][TaCl_6]$ , a sandwich compound (OEP = octaethylporphyrin). Half-sandwich alkyl Ta compounds including a cationic species were also prepared.<sup>13</sup>

### 2.2.2 Alkoxides

Homoleptic alkoxides (see *Homoleptic Compound*)  $M(OR)_5$  (**3**;  $R = Me, Et, Pr$ , etc.) derive from  $MCl_5$  by

reaction with alcohols (the reaction is driven to completion by a base that acts as proton acceptor) or with alkali alkoxides (equation 4) or from anodic dissolution of the metal in alcohol.<sup>1</sup> Transesterification reactions extend the range of available alkoxides, giving, for instance, trialkylsiloxides  $M(OSiR_3)_5$  and heteroleptic alkoxides  $M(OR)_{5-x}(OR')_x$  (see *Heteroleptic Compound*).

Alkoxides are usually highly soluble, volatile, monomeric ( $R = 2,6$ -dialkylaryl) or dimeric ( $R = Me, Et, Ph$ ), depending on the size of the  $R$  group. The terminal  $M-OR$  bond lengths (about  $1.90 \text{ \AA}$ ) are shorter than the sum of the covalent radii ( $2.27 \text{ \AA}$ ). This suggests electron donation from oxygen  $p_\pi$  orbitals to the metal empty  $d_\pi$  orbitals [ $O(p_\pi) \rightarrow M(d_\pi)$ ] and thus  $\pi$ -bonding (see  *$\pi$ -Bond*).  $\pi$ -Bonding is confirmed by rather large  $M-O-C$  angles. Despite a high thermodynamic stability, the  $M-OR$  bond is labile; for the dimers, bridges may open and close reversibly, leading to fluxional behavior in solution. The electroattractive OR groups make metal alkoxides very prone to nucleophilic attack (see *Fluxional Molecule*) and they react with a variety of organic hydroxy derivatives such as  $\beta$ -diketones (see *Diketones*), thio- $\beta$ -diketones,  $\beta$ -hydroxyesters, diols and polyols, silanols, alkoxyamines, Schiff bases (see *Schiff Base*), and simple and functional, including polymerizable, carboxylic acids.<sup>14,15</sup>

Metal alkoxides are extremely sensitive to hydrolysis, and one of their applications is their use as precursors for advanced materials via hydrolysis–polycondensation reactions and the formation of polynuclear oxoalkoxides as intermediates in the *sol–gel* process (see *Sol–Gel Synthesis of Solids*). Most of their modification by hydroxy derivatives has been related to the need to reduce their reactivity for those applications.<sup>16</sup> Their volatility, comparable to the  $\beta$ -diketonates, makes them suitable for the elaboration of coatings by MOCVD.<sup>16,17</sup> By contrast with the pentahalides, alkoxides (**3**) do not easily form complexes with Lewis bases, although complexes can be detected in solution in the presence of the parent alcohol or hard donors (amines, phosphine oxides) (see *Hard & Soft Acids and Bases*). However, they react easily with other metallic derivatives (alkoxides, carboxylates,  $\beta$ -diketonates, etc.) giving heterometallic (mixed-metal) oxo or non-oxoalkoxides.<sup>14–17</sup> Such derivatives are attractive precursors for ternary or quaternary oxides by *sol–gel* reactions as they allow homogeneity to be achieved at a molecular level and their structure may preform the macromolecular framework of the ceramic.  $[LiNb(OEt)_6]_\infty$  (**4**) and (**5**) are examples of compounds having structures related to the materials lithium niobate and  $M'Nb_2O_6$  ( $M' = Mg, Cd, Pb$ ), respectively. Scheme 1 collects some of their reactivity patterns.

**Scheme 1** Some examples of the reactivity of  $M(OR)_5$  (all reactions at rt unless otherwise stated)

$[Nb(OR)_5]_2$  ( $R = \text{Me, Et, allyl}$ ) react reversibly with carbon dioxide to form an O,O-hemicarbonate (**6**) then the organic carbonate.<sup>18</sup>  $Ta(OEt)_5$  was reported as a catalyst for lactide polymerization whereas  $(EtO)_2TaL$  ( $L = \text{tris}(2\text{-oxy-3,5-dimethylbenzyl})\text{amine}$ ) failed to act as a single site initiator.<sup>19</sup> The homoleptic Nb and Ta alkoxides have also been used for access to mesoporous (*see Porous Inorganic Materials*) oxides using surfactants,<sup>20</sup> or to nanostructured oxides using organogelators as structure-directing agents.<sup>21</sup> Mesoporous  $Nb_2O_5$  could be converted into a metallic niobium oxide molecular sieve which, reacting at rt with  $N_2$  to form a nitride, provides the first example of such a process mediated by a molecular sieve.

Halide alkoxides  $M(OR)_{5-x}X_x$  ( $x = 1-4$ ,  $X = \text{Cl or Br}$  mainly) result essentially from reaction of  $MX_5$  with ROH or with trimethylsilyl reactants. They display reactivity patterns comparable to (**3**) but they are more prone to form complexes.  $M(OR)_4Cl$  species are the least common. The most relevant results in organometallic chemistry of Nb and Ta have been associated with ancillary, bulky alkoxide ligands (*see Niobium & Tantalum: Organometallic Chemistry*).<sup>22</sup> Of particular interest are the halide alkoxides based on groups such as 2,6-alkylaryloxides<sup>14</sup> or tri-*t*-butylsiloxide.<sup>14,23</sup> They are able to sterically saturate metal centers in monomers while leaving them electron deficient (*see Electron Deficient Compound*), and unusual structural and reactivity patterns have been observed in different oxidation states. Substitution reactions of the halides afforded alkylaryloxides, which catalyze the hydrogenation of arylphosphines. Stable aryloxide hydrides such as  $TaH_2(2,6\text{-}t\text{Bu}_2\text{C}_6\text{H}_3\text{O})_2Cl(\text{PMe}_2\text{Ph})_2$  for instance have been isolated.<sup>14,24</sup> They react with olefins

and alkynes, the product depending on the ancillary ligand. A  $Ta^V$  hydride showing hydrodeoxygenation (HDO) of the tridentate aryloxide has been reported.<sup>25</sup> The isolation of  $Ta^V$  species containing resolved 3,3'-disubstituted-1,1'-bi-2,2'-naphthoxides has been achieved with chloride or dimethylamide as ancillary ligands.<sup>26</sup> Nb aryloxides associated with  $AlR_3$  or *Grignard Reagents* are catalyst precursors for the polymerization of monoalkyl-substituted alkynes. The bulkiness around the metal (controlled by the number of OAr-ligands) prevents side reactions and enhances the molecular weight (MW) of the polymer.<sup>14</sup> The reduction of  $(\text{silox})_3TaCl_2$  under  $H_2$  offered a mononuclear dihydride (**7**) in high yield (equation 5).<sup>24</sup> The presence of terminal hydride ligands for (**7**) is supported by a vibration at  $1725\text{ cm}^{-1}$  in the IR and a signal at low field in the NMR (*see Hydride Complexes of the Transition Metals*).

*Calix[4]arenes* have been used as a preorganized set of O-donor atoms. Monomeric or dimeric species were obtained depending on the calixarene substituents.<sup>27</sup> They were used to develop the organometallic chemistry of Nb and Ta in various oxidation states, the electron reservoir of the  $Nb=Nb$  bond is able to activate small molecules including  $N_2$  (*see Niobium & Tantalum: Organometallic Chemistry*).

### 2.2.3 Diketonates, Carboxylates, and Related Derivatives

Homoleptic pentavalent  $\beta$ -diketonates are unknown, the volatility of heteroleptic derivatives such as  $M(\text{thd})_4X$  ( $X = \text{Cl}, \text{OR}$ ) allows their use as a source of the metal oxides in MOCVD.<sup>16,17</sup> Ionic species such as  $[\text{Ta}(\text{thd})_4][\text{TaCl}_6]$  have also been obtained.

The reaction between pentahalides or alkoxides and carboxylic acids gives oxochloro- or oxoalkoxocarboxylates. Chiral tantalum cyclopentadienyl carboxylates mediate acylation reactions of amides, giving dipeptides in good yield with high stereochemical purity.<sup>28</sup>

Derivatives of heterocyclic carboxylic or  $\alpha$ -hydroxyacids have been obtained in aqueous media. For instance, niobic and tantallic acids dissolve in aqueous solutions of oxalic acid giving mono-, bis-, or trisoxalato compounds, depending on pH and concentrations.<sup>1,2</sup> The species isolated for Nb are oxoalato derivatives with the oxo ligand in the axial position of a pentagonal bipyramid (*see Pentagonal Bipyramid*).<sup>1</sup> The solubility of  $\text{Ta}_2\text{O}_5$  in oxalic acid solutions is much lower than that of  $\text{Nb}_2\text{O}_5$  due to polymeric species. The intense coloration of the complexes formed with ligands such as 4-(2-pyridylazo) resorcinol or ascorbic acid are interesting for the spectrophotometric determination of Nb or Ta.<sup>1,2</sup> (*see Analytical Chemistry of the Transition Elements*). Compounds with inorganic oxyanions (*see Oxoanion*) (nitrates, sulfates, phosphates, etc.) have been reported. The interest in the sulfates arises from processes using sulfuric acid in the treatment of minerals.<sup>1</sup> Various sulfato species (mainly oxo ones) were isolated from the  $\text{M}_2\text{O}_5\text{--SO}_3\text{--H}_2\text{O}$  system.<sup>1</sup> The coordination polyhedron of  $\text{K}_7\text{M}(\text{SO}_4)_6$ , obtained from solutions of  $\text{M}_2\text{O}_5$  in molten  $\text{K}_2\text{S}_2\text{O}_7$ , consist of six monodentate sulfato ligands.<sup>2</sup> Crystalline phosphate hydrates display a layer structure able of hosting various molecules.<sup>1</sup> An  $\text{NbX}_6^-$  anion based on the 'teflate'  $\text{OTeF}_5$  ligand has been reported; the steric hindrance provides kinetic stabilization in the presence of electrophilic cations that might expand its use as a counterion (*see Counter Ions*).

## 2.3 Complexes with Sulfur, Selenium, and Tellurium Donors

Numerous neutral complexes of the pentahalides with S-donors have been described. Anionic S-donor ligands are mainly represented by sulfides ( $\text{S}^{2-}$ ), disulfides ( $\text{S}_2^{2-}$ ), thiolates ( $\text{RS}^-$ ), dialkyldithiocarbamates ( $\text{R}_2\text{dtc} = \text{S}_2\text{CNR}_2^-$ ; *see Dithiocarbamate*), and dialkyl thiophosphates ( $\text{S}_2\text{P}(\text{OR})_2^-$ ) (*see S-donor Ligands*).

### 2.3.1 Thio-, Seleno- and Tellurohalides Derivatives

Thio- and selenohalides  $\text{MEX}_3$  ( $E = \text{S}, \text{Se}$ ) are accessible by the reaction of antimony chalcogenides with pentahalides at rt in  $\text{CS}_2$ .  $\text{NbSCl}_3$  can also be conveniently obtained by reacting the pentachloride with hexamethyldisilathiane

in  $\text{CH}_2\text{Cl}_2$ .<sup>1,2</sup> the reaction is comparable to that depicted in equation (3). A few neutral mono or bis adducts of the thiohalides have been described. X ray has established the presence of a terminal  $\text{Nb}=\text{S}$  bond (2.09 Å). Vibrations of the  $\text{M}=\text{S}$  moiety in the IR have been reported around  $550\text{ cm}^{-1}$  for Nb, while a wider range ( $435\text{--}505\text{ cm}^{-1}$ ) has been observed for the tantalum derivatives. Multidendate amino ligands  $[(\text{NH})_3\text{N} = (\text{Me}_3\text{SiNHC}_3\text{H}_6)_3\text{N}]$  allowed to stabilize  $\text{TaE}(\text{N}_3\text{N})$  derivatives ( $E = \text{S}, \text{Se}, \text{Te}$ ) prepared by reacting the Ta chloroamide and  $(\text{THF})_2\text{LiESi}(\text{SiMe}_3)_2$ .<sup>3</sup> The one-dimensional solid  $[\text{Ta}(\text{Te}_2)_4][\text{PtI}_6]\text{I}_2$  synthesized from the elements at high temperature consists of  $[\text{Ta}(\mu, \eta^2\text{-Te}_2)_2]$  chains separated by  $\text{PtI}_6$  groups and iodine atoms.<sup>3,4</sup>

### 2.3.2 Thiolate, Dithiocarbamate Derivatives, and Chalcogenometallates

Anionic six-coordinate homoleptic thiolates were isolated with monodentate arenethiolate or with bidentate ethylene-1,2-dithiolate ligands and with various cations.<sup>29</sup> The coordination sphere often tends toward a trigonal prismatic geometry (*see Trigonal Prism*), as observed for  $[\text{Nb}(\text{SC}_2\text{H}_4\text{S})_3]^-$  or for  $[\text{Nb}(\text{SC}_6\text{H}_4\text{Me-}p)_6]^-$ . Neutral homoleptic thiolates  $\text{M}(\text{SR})_5$  are limited ( $R = \text{C}_6\text{F}_5$  or  $\text{SC}_6\text{H}_3\text{Me}_2\text{-}2,6$ ). The Nb arylthiolate was converted into  $\text{NbS}_2$  by thio sol-gel whereas it acted as a precursor to NbS films by chemical vapor deposition (CVD).<sup>30</sup> Oxo- and halothiolates have also been reported. X-ray data have shown that the extent of the S to M  $\pi$ -bonding in these electron-deficient thiolates is reduced compared to the O to M  $\pi$ -bonding in aryloxides. Reactions with thiolates (equation 6) or dialkyldithiocarbamates are often versatile and compounds having  $\text{M}=\text{S}$  or  $\text{M}(\text{S}_2)$  bonds might be obtained by activation and cleavage of the C–S bond.<sup>1,29</sup> These reactions are dependent on the experimental conditions;<sup>1</sup> they might be assisted by water and be relevant to hydrodesulfurization (*see Hydrodesulfurization & Hydrodenitrogenation*). Niobium sulfido and bis-sulfido dithiocarbamates were obtained by reacting  $\text{NbO}(\text{dtcEt}_2)_3$  with boron sulfide.<sup>4,29</sup>

Homoleptic Ta dithiocarbamates result from Insertion of  $\text{CS}_2$  into the tantalum–nitrogen bond of  $\text{Ta}(\text{NR}_2)_5$ ; in the case of niobium, similar reactions proceed with reduction to  $\text{Nb}^{\text{IV}}$ .<sup>1</sup> Halodithiocarbamates can be either molecular or ionic and the existence of Coordination Isomers  $\text{NbCl}_3(\text{Et}_2\text{dtc})_2$  and  $[\text{Nb}(\text{Et}_2\text{dtc})_4][\text{NbCl}_6]$  has been established.<sup>2,31</sup>  $^{93}\text{Nb}$  NMR spectroscopy has been used to identify the various dithiocarbamates in solution. The dithiocarbamate ligand is bidentate and its small bite (*see Bite Angle*) favors high coordination numbers of seven or eight.

**Figure 3** Structure of the  $M_6S_{17}^{4-}$  thiometallates. The bond length order is  $M-S$  terminal  $< M-\mu S < M-\mu_3-S < M-S_b$  ( $S_b$  being inside the cage)

The lability of the pentalkoxides has been exploited for the synthesis of *Thiometallates* at rt. This is an interesting alternative to the high-temperature reaction between the elements, often difficult to control. Hexamethyldisilathiane is used as a source of sulfur, and soluble  $[MS_4]^{3-}$  (**8**) and  $[M_6S_{17}]^{4-}$  (Figure 3) salts were obtained depending on the counterion (equation 7).  $Li^+$  allows the stabilization of small, highly charged, nucleophilic  $[MS_4]^{3-}$  species, the simplest chalcogenoniobates and -tantalates structurally characterized.<sup>1,29</sup>

Thiometallates (**8**) and  $Ta_6S_{17}^{4-}$  serve as synthons, for instance, for the preparation of mixed-metal clusters involving iron<sup>2</sup> or copper and silver, respectively.<sup>1,32</sup> The discrete polynuclear  $Ta_2S_{11}^{4-}$  and  $Nb_4Se_{22}^{6-}$  anions, prepared by traditional solid-state routes, have a structure related to that of polynuclear Mo oxysulfide anions. Nb–Cu chalcogenido clusters stabilized by phosphines could be prepared directly from  $NbCl_5$  (equation 8). The anion (**9**), for instance, is based on two  $Cu_3NbS_3Cl$  heterocubane units linked by three  $\mu_3$ -chlorine.<sup>33</sup>

Soluble mixed-chalcogenido Nb/Se/E complexes ( $E = S, O$ ) have been reported.<sup>34</sup> The differences in structures and *coordination geometries* between sulfides and selenides as ligands for Nb have been attributed to their redox properties as well as to size. The presence of terminal Se–H ligands in the metal coordination sphere might be due to the need to avoid accumulation of excessive negative charge around the  $Nb(Se)_3L^{2-}$  units ( $L = SH, SeH, OMe$ ).

A variety of sulfide and selenide clusters have been obtained from  $CpMCl_4$  and silylated or Li chalcogenides.<sup>32</sup> The  $Cp^*TaS_3^{2-}$  unit offers an example of a moiety with three terminal sulfides that might serve as a building block for more complex structures.<sup>9</sup> The presence of the bridging pentasulfide  $\mu, \eta^2-S_5^{2-}$  ligand, derived from octasulfur, has been established by X-ray diffraction in dinuclear anionic or neutral niobium derivatives such as  $[Nb_2(OMe)_2(\eta^2-S_2)_2(\mu, \eta^2-S_2)(\mu-O)(\mu-\eta^2-S)_5]^-$ .<sup>2,9,35</sup>

## 2.4 Nitrogen Donors

Anionic N-donor ligands comprise essentially amido ( $NR_2^-$ ), imides or nitrenes ( $NR^{2-}$ ); amidinates or guanidinates  $[(RN)_2CX^-]$ ,  $X = R'$  or  $NR'$  respectively]; azides ( $N_3^-$ ); or nitrides ( $N^{3-}$ ).

### 2.4.1 Amido and Imido Derivatives

Homoleptic  $Nb^V$  and  $Ta^V$  dialkylamides,  $M(NR_2)_5$ , have been obtained from the pentahalides and lithium amides. By contrast with alkoxides, they are generally monomers (even for  $NMe_2$ ) as a result of the steric demand of the dialkylamido ligand. They are volatile but less stable thermally than the pentaalkoxides. The steric congestion around the metal is reduced during thermolysis by loss of ligands. This is achieved for niobium by reduction to  $Nb(NR_2)_4$  (favored by the length of the alkyl chain); in the case of tantalum, oxidation state V is retained and the pentaamides are converted into a mixed imido amide  $Ta(NR)(NR_2)_3$  (**10**) (equation 9). Formation of the imide ligand occurs through  $\beta$ -H abstraction and intramolecular metallation although *Cyclometallation* reactions are uncommon with metals having a  $d^0$  electronic configuration (see *Electron Configuration*). The azametallacycle (**11**) was isolated and used as a MOCVD metal source for obtaining films of cubic TaN as well as of amorphous  $Ta_2O_5$  at low temperature.<sup>35</sup>

**Scheme 2** Some reactions of  $\text{Ta}(\text{NMe}_2)_5$  (all reactions at rt unless otherwise stated)

**Scheme 3** Synthesis and reactivity of chloroimide complexes

Halodialkylamido derivatives are accessible by several methods, especially reactions between pentahalides and amines or trimethylsilyl reactants. They are obtained as dimers or as monomeric adducts in the presence of an excess of amines. A common feature of these derivatives is the hexacoordination of the metal. The  $\text{MNC}_2$  units are planar with short  $\text{M}-\text{N}$  distances ( $\approx 1.86 \text{ \AA}$ ), and thus suggest strong  $\pi$ -bonding by interaction of the nitrogen  $p_\pi$  orbitals and empty  $d_\pi$  orbitals of the metal.

The  $\text{M}-\text{NR}_2$  bond is labile and Nb and Ta dialkylamides  $\text{M}(\text{NR}_2)_5$  (**12**) are valuable starting materials (Scheme 2). They can easily undergo substitution or *Insertion* reactions. Insertion of  $\text{CO}_2$ ,  $\text{CS}_2$ , and  $\text{COS}$  in  $\text{M}(\text{NR}_2)_5$  has been observed, giving dialkylcarbamates, dithiocarbamates, or monothiocarbamate derivatives, respectively. In the case of niobium, the insertion of  $\text{CS}_2$  is accompanied by reduction. Insertion of  $\text{CO}_2$  is catalyzed by amines resulting from adventitious hydrolysis. Monodentate as well as bidentate carbamate

ligands have been observed by X ray and can be distinguished in solution by IR, but not by NMR owing to fluxionality.<sup>9,36</sup> Nb and Ta derivatives based on bidentate or polydentate amido ligands have been reported. (**12**) allowed access to the first tantalasilsesquioxanes (**13**) (see **Silicon: Organosilicon Chemistry**).<sup>37</sup> (**12**) are source to guanidinate(−1) (**14**) or to guanidinate(−2) complexes by reaction with carbodiimides, or by protonation of the amido groups with trialkylguanidines respectively.<sup>38</sup> The acidic carborane *nido*- $\text{C}_2\text{B}_9\text{H}_{13}$  (see **Boron: Metallocarboranes**) reacts with (**12**) to generate three-legged piano stool  $\text{M}(\text{C}_2\text{B}_9\text{H}_{11})(\text{NMe}_2)_3$  complexes (**15**), where the dicarbollide acts as a *spectator ligand*.<sup>39</sup>

Imido ligands are implicated in catalytic processes; they may act as  $\text{NR}$  transfer reactants or as intermediates on chemical routes to nitrides by CVD. Among the variety of routes available, reactions between  $\text{MCl}_5$  and primary amines (Scheme 3), trimethylsilyl or lithium reactants and aminolysis of  $\text{M}(\text{NR}_2)_5$  with primary amines are the most selective

ones. The formation of the  $M\equiv NR$  bond proceeds via H abstraction. It is favored by proton acceptors, either excess of the amines, of ligands such as phosphines, or of an inorganic base (silicates,  $ZnCl_2$ , ...) <sup>40</sup> and many efforts have been devoted to high-yield syntheses of  $M(NR)Cl_3L_x$  complexes ( $R = Ar$ ,  $tBu$ ,  $SiMe_3$ ) with labile, inert ligands. The donor capability of the various  $R$  groups have been compared,  $tBu$  is more efficient toward  $d^0$  metals than  $SiMe_3$ , itself better than the  $Cp$  ligand. <sup>41</sup> Decomposition patterns of chloroimide complexes have been examined in relation to CVD of metal nitrides. <sup>8</sup> The decomposition of  $MNCl_2$  into  $NbN$  and  $Ta_3N_5$  respectively, is consistent with the CVD results.

The reaction between  $Ta(NMe_2)_5$  and silanes yielded an unusual dihydride imine complex (**17**) through  $\beta$ -H abstraction between amide ligands (equation 10). <sup>42</sup> The first  $Cp$ -free silyl (**18**) and disilyl  $Ta$  derivatives have been reported. They are potential precursors to  $Ta$ - $N$ - $Si$  ternary materials. Unusual oxidation products such as (**19**) could be stabilized (equation 11). <sup>43</sup>

Imido amides or imido alkoxides are known, especially with bulky  $NAr$  groups. <sup>1,22</sup> Their utility has been demonstrated in the preparation of  $M^{III}$  imido alkyne compounds. The electrophilic, transient  $(t-Bu_3SiNH)Ta(=NSi-t-Bu_3)_2$  was active in hydrocarbons  $C-H$  activation reactions. <sup>22</sup> Metal-imide bonds are short (1.75 Å) with  $M-N-C$  angles close to linearity. These data are consistent with an  $M-N$  Bond Order somewhat greater than two, and reflect the  $\pi$  donation of the nitrogen lone pair with a formal bonding  $M\equiv NR$ , the imido ligand being described as a 4e donor. In the imido alkoxides, the  $OR$  ligand is oriented *cis* to the imide, thus allowing to maximize the number of interactions between these ligands, and the  $d^0$  metal is thus able to reach 18e (see *Effective Atomic Number Rule*).

The oxo and organoimide ligands are *Isoelectronic*, but imides have higher thermal stability and solubility than their oxo analogs. They are characterized by a vibration around  $1350\text{ cm}^{-1}$  in the IR. <sup>15</sup>N NMR data have been reported for  $M^V$  and  $M^{III}$  imides, the latter appear at higher fields. The action of alcohols generally removes the imido ligand, giving alkoxides, while that of carboxylic compounds results in the formation of oxo derivatives. <sup>1</sup>

#### 2.4.2 Dinitrogen Activation

Niobium and tantalum belong to the metals that are able to bind dinitrogen. <sup>44</sup> The development of this area was first due to Schrock and coworkers, who in 1982 could obtain stable tantalum  $\mu$ - $N_2$  compounds in high yields by reducing *Alkylidene* complexes under dinitrogen at normal pressure. <sup>1,22</sup> This route can be circumvented in a 'single pot' synthesis by reacting the pentahalides with silylated hydrazines (equation 12).

Complexes (**20**) and (**21**) are *synthons*, either by *Ligand* exchange or by chlorine substitution. The latter reactions offered, for instance, thiolate or diethyldithiocarbamate (**22**) derivatives (Figure 4); the first dinitrogen complexes in which the coligands are exclusively S-donors, significant in light of the predominant sulfur ligation of the enzyme nitrogenase (see *Nitrogenase: Metal Cluster Models*).

The usual structural feature of  $Nb$  or  $Ta$  nitrogen complexes is the presence of a bridging  $\mu$ - $\eta^2:\eta^2$  dinitrogen ligand (see *Bridging Ligand*) involved in a nearly linear  $M-N-N-M$  arrangement. The  $N-N$  bond lengths (1.39–1.25 Å) are longer than in free dinitrogen ( $N\equiv N$ , 1.0976 Å), suggesting a bond order between one and two. The  $M-N$  bonds (1.85–1.75 Å) are also much shorter than the usual  $M-N$  single bond (typically 1.95–2.05 Å) and close to the

**Figure 4** Molecular structure of the dinitrogen complex  $Nb_2(\mu-N_2)_2(dtcR_2)_6$  (**22**)

distances found in imido derivatives. As a result, these dinitrogen complexes, which are specific for early transition metals, have been formulated as  $M=N=N=M$  systems or hydrazido(4-) derivatives.  $^{15}\text{N}$  labeling has established that the  $\text{Ta}=\text{N}=\text{N}=\text{Ta}$  group is characterized in the IR by an absorption around  $845\text{ cm}^{-1}$ , consistent with partial reduction of  $\text{N}_2$ . This description of the  $M\mu\text{-N}_2$  bridge is supported by the reactivity of these adducts, which behave as imido complexes. Protonation of bridging dinitrogen by various hydric acids gives hydrazine only (equation 13) and has been studied kinetically in the dithiocarbamates (**22**).<sup>44</sup> In the presence of excess acid, protonation proceeds irreversibly via hydrazido(2-) complexes that have been detected in the case of niobium (Scheme 4).<sup>1,2,9</sup> Ta complexes containing the methylhydrazido(1-) ligand have been studied with the aim of understanding the role of related derivatives as intermediates in the conversion of hydrazido(2-) complexes to hydrazine. A 4e reduction of  $\text{N}_2$ , as well as further reduction into a nitride, has also been achieved with a  $\text{Nb}^{\text{III}}$ -calix[4]arene containing a very reactive  $\text{Nb}=\text{Nb}$  unit.<sup>45</sup> Cleavage of  $\text{N}_2$  was also promoted by the low-valent species derived from the reduction of  $[\text{Nb}(\text{R}^-\text{L})\text{Cl}_2]_2$  ( $\text{R}^-\text{L}^{3-}$  = linked aryloxide). The reactions are dependent on the nature of the R substituent.<sup>46</sup>

A facile process for the preparation of Nb and Ta dinitrogen complexes supported by aminophosphine ligands was reported recently.<sup>47</sup> The reaction of the  $\text{Ta}^{\text{IV}}$  diamagnetic hydride  $[\text{NPN}]_2\text{Ta}_2(\mu\text{-H})_4$  (**23**) ( $[\text{NPN}] = \text{PhP}(\text{CH}_2\text{SiMe}_2\text{NPh})_2$ ) with  $\text{N}_2$  provided a  $\text{Ta}^{\text{V}}$  species (**24**) with an unprecedented side-on end-on dinuclear bonding mode. The N-N distance ( $1.319\text{ \AA}$ ) is consistent with the bridging dinitrogen as  $(\text{N}_2)^{4-}$ . The hydride ligands force the metal centers so close together ( $\text{Ta}\cdots\text{Ta}$   $2.830\text{ \AA}$ ) that the usual end-on dinuclear bonding mode becomes impossible (Scheme 5). This strongly activated  $\text{N}_2$  is amenable to functionalization such as Si-N (**25**) or B-N (**26**) bond formation for instance.

#### 2.4.3 Miscellaneous

The azides and nitrides (see *Nitrogen: Inorganic Chemistry*) further illustrate the ability of niobium and tantalum to form M-N multiple bonds. The stability of the azides, although poor, is higher for Ta and for ionic derivatives than for Nb and neutral ones.<sup>1</sup> Their M-N distances are longer than expected for a single bond. Reactions analogous to the Staudinger reaction (see *Phosphorus: Organophosphorus Chemistry*), giving compounds containing the phosphineiminato  $\text{M}=\text{N}=\text{P}$  group,

are the salient feature of their reactivity. These heteroimido derivatives could also be obtained from penta- or oxyhalides and trimethylsilyl or lithium reagents.<sup>48</sup>

Nitrides can be obtained by decomposition of the azides, but thermolysis of the pentahalides with ammonium salts appears more general. Recent synthetic pathways involve the cleavage of  $\text{N}_2$ <sup>45</sup> or decarboxylation of a Nb isocyanate.<sup>49</sup> The solid-state characterization of the  $[\text{M}_2\text{NX}_{10}]^{3-}$  anions shows a linear symmetrical  $\text{M}=\text{N}=\text{M}$  bridge. Neutral halide nitrides are polymeric.<sup>1,2</sup> Heterometallic nitrides based on a corner-shared double cube  $\text{NbTi}_6\text{N}_8$  core (**27**) have been described (equation 14).<sup>50</sup>

A number of pentavalent trispyrazolylborate derivatives (see *Tris(pyrazolyl)borates*) have been reported, especially for niobium.<sup>51</sup> Most of them are monomeric  $\text{Tp}^*\text{MCl}_2\text{X}$  ( $\text{X} = \text{O}, \text{NR}$ ) derivatives.  $\eta^1$  and  $\eta^2$ -pyrazolato (**16**) or 1,2,4-triazolato derivatives have been prepared as potential sources of nitrides for CVD.<sup>52</sup> The reactions between dilithium 1,4-diaza-1,3-diene and pentachlorides have been investigated.<sup>53</sup>

*Ammonolysis* of  $\text{NbBr}_5$  followed by heat treatment was used for access to ceramics, that is, nitrides or carbonitrides. Applied to Ta alkyl derivatives, ammonolysis provides a low temperature route to  $\text{TaN}$ ; the cubic form is obtained instead of the more stable hexagonal one.<sup>54</sup> Similar reactions for  $\text{Cp}^*\text{TaMe}_4$  give a cyclic trimer (**28**) (equation 15), whose delocalized six-membered ring ( $\text{Ta}-\text{N}$  av.  $1.88\text{ \AA}$ ) is related to that of phosphazenes (see *Phosphorus-Nitrogen Compounds*). The thermal ring opening of the chloride analog of (**28**) offered the first soluble polymer based on a Ta-N backbone.<sup>2,3</sup>

**Scheme 4** Mechanism of the production of bridging dinitrogen in niobium and tantalum dithiocarbamate complexes ( $\text{R}_2\text{dtc}$ , etc. Omitted for clarity)

**Scheme 5** Activation and functionalization of dinitrogen by Ta derivatives<sup>47</sup>

Neutral and anionic *Pseudohalide* complexes have been reported. While most of the thiocyanates were considered to be N-coordinated,  $^{93}\text{Nb}$  NMR spectra of  $\text{Nb}(\text{NCS})_6^-$  were reinterpreted in terms of a mixture of N- and S-coordinated isomers.<sup>1,2</sup>

## 2.5 Phosphorus and Arsenic Donors

$\text{Nb}^{\text{V}}$  and  $\text{Ta}^{\text{V}}$  derivatives are hard acids and their complexes with P- or As-donors are limited. Tertiary phosphines, especially  $\text{PMe}_3$ , have been widely used to stabilize low-valent derivatives. C–H activation reactions, promoted by the formation of thermodynamically stable Ta–H, Ta–C, and Ta=C bonds have resulted in metallacycles based on unusual anionic phosphorus donors.<sup>22</sup> Nucleophilic  $\text{Ta}^{\text{V}}$  phosphinidene complexes could be stabilized by a tripodal tetradentate  $[\text{NN}_3]$  amido ligand.<sup>9,55</sup> The terminal PR ligand reacts smoothly with aldehydes, providing a general synthesis of phosphalkenes  $\text{RP}=\text{C}(\text{H})\text{R}'$  and act thus as a phospho-Wittig reactant (see **Phosphorus: Organophosphorus Chemistry**).

## 3 OXIDATION STATE +IV

The niobium and tantalum tetrahalides  $\text{MX}_4$  are all known, except  $\text{TaF}_4$ , whose nonexistence is consistent with the fact that  $[\text{TaF}_5]_4$  should be the least reducible halide of these elements.<sup>1</sup> They are dark solids, obtained by reduction of the pentahalides by  $\text{H}_2$  or more often by metals (Al or M) at high temperatures. With the exception of  $\text{NbF}_4$ , all tetrahalides disproportionate thermally (see *Disproportionation*); this can be overcome by a high pressure of the pentahalides during the preparation. Except  $\text{NbF}_4$ , they are all essentially diamagnetic (see *Diamagnetism*) as a result of a one-dimensional (1D) polymeric structure based on dinuclear  $\text{M}_2\text{X}_8$  units with two types of metal bridging (short and long), being responsible for their semiconducting properties (see *Semiconductors*).

### 3.1 Halogens as Ligands: Tetrahalides and their Adducts

Numerous adducts, mostly of type  $\text{MX}_4\text{L}_2$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ), are known with nitrogen, phosphorus, arsenic, oxygen, and sulfur donors. They are synthesized by reaction of solid tetrahalides with the ligand or by reduction of pentahalides with the ligand, mainly bidentate or heterocyclic N-donors or phosphines.  $\text{NbCl}_4(\text{THF})_2$  (**29**) is of particular value since the lability of the THF molecules makes it a useful *synthon* in  $\text{Nb}^{\text{IV}}$  chemistry.

The  $\text{MX}_4\text{L}_2$  adducts with monodentate ligands are generally monomeric, and thus paramagnetic (see *Paramagnetism*). In the absence of X ray, electron spin

resonance (ESR) (see *Electron Paramagnetic Resonance*) can be used to gain structural information. The ESR spectra of the Nb derivatives, for instance, are characterized by 10 lines as a result of the coupling of the unpaired electron with the metal of spin  $I = 9/2$ . The hyperfine coupling parameters of the  $d^1$  distorted octahedral  $\text{MX}_4\text{L}_2$  complexes generally decrease with increasing ligand basicity. Reduction of  $\text{NbCl}_5$  with primary phosphines (equation 16) gave dinuclear diamagnetic  $\text{Nb}^{\text{IV}}$  adducts (**30**) whose structure is similar to that of the  $\text{Nb}_2(\mu\text{-Cl})_4\text{Cl}_4(\text{PR}_3)_4$  derivatives obtained from  $\text{NbCl}_4$ .<sup>1</sup> (**30**) were used as precursors to NbP films by CVD.<sup>56</sup> Octacoordination is also found for monomeric  $\text{MX}_4$  bisadducts involving bidentate ligands such as  $\text{MCl}_4(\text{dmpe})_2$ , which have been widely used for access to lower oxidation states.

### 3.2 Solvolysis Products of the Tetrahalides

Compounds that can be considered as *Solvolysis* products from the tetrahalides can result from direct substitution reactions of  $\text{MX}_4$  or their complexes but also from the reduction of  $\text{M}^{\text{V}}$  derivatives or from oxidative addition of  $\text{M}^{\text{III}}$  complexes especially in the case of Ta.<sup>1</sup>

$\text{Nb}^{\text{IV}}$  alkoxides were first reported to form during the electrochemical synthesis of  $\text{Nb}(\text{OEt})_5$ , starting from the metal or during the electrolytic reduction of  $\text{NbCl}_5$  in alcohols. Alcoholysis of  $\text{Nb}(\text{NR}_2)_4$  generally leads to  $\text{Nb}(\text{OR}')_5$ , but oxidation state IV could be retained with bulky  $\text{R}'$  groups such as adamantyl. Structurally characterized diamagnetic dimeric Nb chloroalkoxides and tetrameric oxochloroalkoxides have been obtained from trivalent halide adducts and alcohols.<sup>1,2,9</sup>  $[\text{Nb}_2(\text{OMe})_9]^-$  results from further substitution. All compounds have a Nb–Nb single bond (2.78–2.89 Å). The first  $\text{Nb}^{\text{IV}}$  enolate has been reported.<sup>57</sup> The reductive coupling of  $\text{Nb}^{\text{V}}$  salophen derivatives led to dimers linked through C–C and Nb–Nb bonds. Each of those bonds can be used as a reversible source of a pair of electrons for reduction, for instance, of diphenyldiazomethane.<sup>58</sup> These reactions offer a close analogy with those observed for the reduced Nb calix[4]arene species.<sup>45</sup>

The reduction of  $\text{MCl}_3(\text{silox})_2$  in the presence of  $\text{H}_2$  (1 atmosphere) gives siloxohydrides (**31**), shown by MW measurements to be dinuclear (Scheme 6).<sup>23,24</sup> Multinuclear NMR ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{29}\text{Si}$ ) and IR account for an unusual geometry: M–M bonding without bridging ligands. The Ta species is able to promote CO deoxygenation, and C–H and C–C bond formation, and thus tracks the

**Scheme 6** Some reactions of the dinuclear Ta<sup>IV</sup> hydrosiloxide (31)

critical sequence of the *Fischer–Tropsch Process* (see *Carbonylation Processes by Homogeneous Catalysis*). The reduction of Nb 2,6- or 2,4,6-aryloxides under H<sub>2</sub> gave  $\eta^4$ -cyclohexadiene complexes by intermolecular hydrogenation. Hydrogenation occurs exclusively at the ortho-Ph group.<sup>14</sup>

Monomeric, paramagnetic chlorohydrides such as MH<sub>2</sub>Cl<sub>2</sub>(PR<sub>3</sub>)<sub>4</sub> derive from facile oxidative addition of H<sub>2</sub> to MCl<sub>2</sub>(PR<sub>3</sub>)<sub>4</sub> complexes. Of these 17e dodecahedral complexes, (32) is the most interesting (equation 17). Its thermolysis in solution offers a quadruply bridged hydride (33) and it can also be reduced to a monomeric Ta<sup>III</sup> 16e species (34).<sup>1,22</sup> Ta<sup>IV</sup> hydrides display a hydridic character (see *Hydride Complexes of the Transition Metals*), as shown by the reduction of CO by cyclopentadienyl derivatives.<sup>1</sup> (see *Niobium & Tantalum: Organometallic Chemistry*)

Homoleptic and chloro  $\beta$ -diketonates have been reported for both metals. They derive from the reaction of  $\beta$ -diketones (or their alkali derivatives) with either M<sup>IV</sup> or M<sup>III</sup> halide complexes. They are generally monomeric and thus paramagnetic; their structures have been proposed on the basis of UV or ESR data and less often X-ray data.

Monomeric, paramagnetic Nb<sup>IV</sup> dialkylamides Nb(NR<sub>2</sub>)<sub>4</sub> have been obtained as highly air-sensitive liquids by spontaneous reduction of the pentaamides. The thermal decomposition of Nb(NEt<sub>2</sub>)<sub>4</sub> in the presence of ammonia gave Nb<sub>3</sub>N<sub>4</sub> films.<sup>35</sup> Whereas Nb<sup>IV</sup> amides (35) can also be obtained from NbCl<sub>4</sub>(THF)<sub>2</sub>,<sup>59</sup> those of Ta<sup>IV</sup> derive mostly from the reduction of Ta(NR<sub>2</sub>)<sub>2</sub>Cl<sub>3</sub> by Na/Hg.<sup>60</sup> Organometallic Nb(NR<sub>2</sub>)<sub>2</sub>R'<sub>2</sub> species as well as compounds based on terdentate diphosphino- and diamidoamido ligands are known for Nb.<sup>5,59</sup> Reaction of (29) with three equivalents of Cy<sub>2</sub>NLi afforded the first Nb<sup>IV</sup> aziridine (36) by metallation of one of the cyclohexyls. Attempts to reduce (36) with LiBEt<sub>3</sub>H under N<sub>2</sub> lead to a Nb<sup>V</sup>–N<sub>2</sub> end-on complex.<sup>61</sup> Scheme 7 summarizes

some examples of the reactivity of NbCl<sub>4</sub>(THF)<sub>2</sub>. An amide based on staggered TaCl(NCy<sub>2</sub>)<sub>2</sub> moieties first considered as a Ta<sup>III</sup> species has been reformulated as a Ta<sup>IV</sup> one, Ta<sub>2</sub>(μ-H)<sub>2</sub>Cl<sub>2</sub>(NCy<sub>2</sub>)<sub>4</sub>, because of hydride ligands.<sup>62</sup> The high reactivity of the dinuclear Ta amide supported by the bulky 9*H*-carbazole is illustrated by its hydrogenolysis giving a hexahydride,<sup>9,22</sup> whose structure is representative of the Ta<sub>2</sub><sup>IV</sup>(μ-H)<sub>4</sub> core observed with the chlorides (33). Eight-coordinate arylformamidinates M[ArNC(H)NAr]<sub>4</sub> have been reported for both metals.<sup>63</sup> Binuclear Nb<sup>IV</sup> bis-pyrazolylborate derivatives are known.<sup>54</sup> A paramagnetic Nb<sub>2</sub>–N<sub>2</sub> complex was obtained by reduction of a Nb<sup>III</sup> chloride precursor supported by a bis-(amidophosphine) [N<sub>2</sub>P<sub>2</sub>] macrocycle.<sup>64</sup>

The unstable Nb(PCy<sub>2</sub>)<sub>4</sub> derived from a Nb<sup>III</sup> precursor remains the only homoleptic dialkylphosphide of those elements.<sup>1</sup> Ta<sup>IV</sup> phosphinidene bridged dimers stabilized by CpR or Cp\* ligands are known.<sup>55</sup>

The few data available on thiocyanates indicate N-coordination in the solid.<sup>1</sup> The octacyanomometallate Nb(CN)<sub>8</sub><sup>4–</sup> has been used for supramolecular magnetic architectures by self assembly with ML<sup>2+</sup> complexes (M = Ni<sup>II</sup>, Mn<sup>II</sup>, L = N-donor macrocycle).<sup>65</sup>

### 3.3 Sulfur, Selenium, and Tellurium Donors: Chalcogenohalides and their Adducts

The interest in the chalcogenides has been stimulated by a possible use of disulfides as cathodes in lithium batteries. Niobium and tantalum homoleptic ME<sub>4</sub> chalcogenides are only stable as tetratellurides; large halide anions are, however, able to stabilize a variety of chalcogenohalides, especially for Nb, the corresponding Ta chemistry being less developed.<sup>2,65</sup> The synthetic and structural chemistry of chalcogenide-rich derivatives is complex. Many of them are low-dimensional solids and display interesting physical properties (see *Chalcogenides: Solid-state Chemistry*). As for most Nb<sup>IV</sup> halides, a common feature is the occurrence of chains in which the metal is present as pairs (alternate short and long Nb–Nb distances, about 3.1 and 3.7–3.9 Å, respectively) that causes diamagnetism as well as semiconducting properties. These chains are connected by a wide variety of fragments. IR and Raman studies established the presence of E–E or M–E

**Scheme 7** Some reactions of  $\text{NbCl}_4(\text{THF})_2$

bonds that were confirmed by X-ray studies. Compounds such as  $\text{NbS}_3$ , for instance, have to be considered formally (they are covalent) as  $\text{Nb}^{\text{IV}}(\text{S}-\text{S})_2^{2-}\text{S}^{2-}$ .

Chalcogenohalides have been synthesized by solid-state high-temperature reactions. A series of isomorphous  $\text{Nb}(\text{E}_2)\text{X}_2$  ( $\text{E} = \text{S}$  or  $\text{Se}$ ,  $\text{X} = \text{Cl}$ ,  $\text{Br}$ ,  $\text{I}$ ) halides have been obtained.<sup>1,2</sup> The molecules may be described as cage-shaped  $\text{Nb}_2(\text{E}_2)_2$  units with  $\mu\text{-}\eta^2\text{:}\eta^2$  dichalcogeno ligands between adjacent Nb atoms and an extended  $[\text{Nb}_2(\mu\text{-E}_2)_2\text{Cl}_{8/2}]_\infty$  structure by sharing all chlorine. The vibrations of the  $\text{S}_2$  groups of  $\text{NbS}_2\text{Cl}_2$  occur at  $588\text{ cm}^{-1}$  in the IR; they are higher than those of the  $\text{Nb}=\text{S}$  group. Chalcogenohalides containing selenium are often mixed-valence (see **Mixed Valence Compounds**)  $\text{Nb}^{\text{IV}}\text{Nb}^{\text{V}}$  derivatives, as established by X-ray and photoelectron spectroscopy (see **Photoelectron Spectroscopy of Transition Metal Systems**).<sup>1</sup> Compounds such as  $\text{Nb}_3\text{Se}_5\text{Cl}_7$  or  $\text{Nb}_6\text{Se}_{20}\text{Br}_6$ , actually  $\text{Nb}_2^{\text{IV}}\text{Nb}^{\text{V}}(\text{Se}_2)_2\text{SeCl}_7$  and  $\text{Nb}_4^{\text{IV}}\text{Nb}_2^{\text{V}}(\text{Se}_2)_{10}\text{Br}_6$ , respectively, illustrate this behavior.  $\text{NbSe}_2\text{Br}_2$  was obtained in conditions that lead to  $[\text{Ta}(\text{Se}_2)_2]_2[\text{TaBr}_6]$  for Ta.<sup>5</sup> The structure of the latter is based on 1D positively charged chains of  $\text{Ta}(\text{Se}_2)_2$  (and thus oxidation state of 4.5 for Ta, which leaves 0.5 e for the Ta-Ta bond) separated by  $\text{TaBr}_6^-$  anions.

$\text{NbS}_2\text{Cl}_2$  has been used as starting material. It gave access to thiocyanates and to  $[\text{Nb}_2(\mu, \eta^2\text{-S}_2)_2(\text{H}_2\text{O})_8]^{4+}$ , the first structurally characterized, in 1997 only, aqua- $\text{Nb}^{\text{IV}}$  complex. The water molecules are labile and the  $\text{Nb}_2(\mu, \eta^2\text{-E}_2)_2^{4+}$  core ( $\text{E} = \text{S}$ ,  $\text{Se}$ ) afforded a new series of  $\text{Nb}^{\text{IV}}$  diamagnetic  $\beta$ -diketonates dithiocarbamates,

dithiophosphates, and xanthates.<sup>66</sup> Depopulation of  $\pi^*$  orbitals leaves the  $\text{S}_2^{2-}$  ligands susceptible to nucleophilic attack giving a product assumed to be  $[\text{Nb}_2(\mu\text{-S})_2(\text{H}_2\text{O})_8]^{4+}$ .

The first Nb or Ta tellurium halide,  $\text{Nb}_2\text{Te}_8\text{I}_{12}$  was described in 1993. Its structure is characterized by two  $[\text{Te}_2(\mu\text{-I})_2\text{I}_4]^{2-}$  ligands coordinated to a  $\text{Nb}_2(\mu\text{-Te}_2)_2^{4+}$  center. The discrete  $\text{Nb}_2\text{Se}_4(\text{Te}_2\text{I}_6)_2$  molecule has a similar structure.<sup>67</sup> New types of structures have been reported for instance for  $\text{Nb}_4(\mu, \eta^2\text{-Te}_2)_4\text{Te}_4\text{I}$ : tetranuclear butterfly clusters are assembled via iodide bridges into 1D infinite chains.<sup>3,4</sup>

Chalcogenide halide adducts obtained directly from  $\text{M}^{\text{IV}}$  compounds remain scarce.  $\text{Nb}_2(\mu\text{-S})_2\text{X}_4(\text{MeCN})_4$  (39), result from reaction between  $\text{NbX}_4$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ) and  $\text{Sb}_2\text{S}_3$  in  $\text{MeCN}$ . Attempts to synthesize  $\text{NbSeBr}_2$  adducts led to reduction of the metal and formation of a mixed valence cluster (40) (equation 18). Formally, two  $\text{Se}^{2-}$  ions form an  $(\text{Se}_2)^{2-}$  ion with release of  $2\text{e}$ , which reduce two  $\text{Nb}^{\text{IV}}$  to  $\text{Nb}^{\text{III}}$  atoms, giving a  $\text{Nb}_2^{\text{IV}}\text{Nb}_2^{\text{III}}$  aggregate. (40) is best described as a central  $(\text{MeCN})_2\text{Br}_2\text{Nb}^{\text{IV}}(\mu, \eta^2\text{-Se}_2)(\mu\text{-Se})\text{Nb}^{\text{IV}}\text{Br}_2(\text{MeCN})_2$  fragment linked by long bromide bridges to two  $\text{NbBr}_3$  units (Figure 5). The tetravalent metals Nb(1) are connected by Nb-Nb bonding but no interaction is observed between the  $\text{Nb}^{\text{III}}$  centers, Nb(2) and Nb(3).

The reaction of  $\text{NbSBr}_3$  in neat THT proceeds with disproportionation; two  $\text{S}^{2-}$  ligands are oxidized to  $(\text{S}_2)^{2-}$

**Figure 5** Molecular structure of the mixed-valence cluster (40)

giving (41) (equation 19). Its most salient structural feature is the Nb( $\mu$ -S)( $\mu$ -S<sub>2</sub>) ring. While similar reactivity patterns were observed for NbSX<sub>3</sub> and other S-donors such as Me<sub>2</sub>S, no evidence for reduction was found in the case of Ta.<sup>1</sup>

The TaCp<sub>2</sub> or Nb(*t*BuC<sub>5</sub>H<sub>4</sub>)<sub>2</sub> moieties allowed to stabilize a number of telluride and selenide units such as Te<sub>*n*</sub><sup>2-</sup> (*n* = 1,4),  $\eta^2$ -TeCH<sub>2</sub>,  $\eta^2$ -Se<sub>2</sub>H, and so on, which were used as ligands toward metal carbonyls.<sup>2,68</sup> <sup>77</sup>Se and <sup>125</sup>Te NMR data were reported.

## 4 OXIDATION STATE +III

The development of the chemistry of niobium and tantalum in their lower oxidation states, three or less, has long been precluded by the lack of convenient starting materials. Indeed, stoichiometric trihalides MX<sub>3</sub> (X = Cl, Br) are only incidental compositions. They are obtained by reduction of the pentahalides or disproportionation of the tetrahalides, and are polymeric and rather inert.

### 4.1 Halogen as Ligands

#### 4.1.1 Anionic and Neutral Complexes: Synthesis and Characterization

A new area in niobium and tantalum chemistry was opened with the discovery that the reduction of MX<sub>5</sub>, MX<sub>4</sub>, or their complexes to yield molecular trihalides can be achieved easily

by reductants such as sodium amalgam in the presence of ligands when carried out in strictly anaerobic conditions. The first trivalent complexes, Nb<sub>2</sub>X<sub>6</sub>(THT)<sub>3</sub> (X = Cl, Br, I), based on tetrahydrothiophene, were obtained in high yield (equation 20) in 1973.

Similar reductive routes allowed to obtain a large variety of soluble Nb and Ta complexes, mostly chlorides, involving monodentate sulfur, nitrogen, or phosphorus donors. The complexes formed can be highly dependent on the experimental conditions, especially the nature of the starting material, of the solvent, or of the reductant. Borohydrides that act as dual reagents can give access to metallic species incorporating various boron ligands.<sup>63,69</sup> The Ta<sup>V</sup> Lewis acid–base adduct (42) (equation 21) with a Li $\cdots$ H–Ta interaction<sup>24</sup> and the *nido*-metalloborane Ta<sub>2</sub>( $\mu$ ,  $\eta^4$ -B<sub>2</sub>H<sub>6</sub>)[ArNC(H)NAr]<sub>4</sub> formed by reacting TaCl<sub>5</sub> with LiBH<sub>4</sub> and *N,N'*-diarylformamidinato lithium are examples of complex reactivity patterns. THF ring opening also can generate unanticipated products such as the Ta<sup>III</sup> [( $\eta^5$ -Cp)<sub>2</sub>Ta( $\mu$ -H)<sub>2</sub>AlH]<sub>2</sub>( $\mu$ -O-*n*-Bu)<sub>2</sub> adduct, where the butoxides bridge the Al centers.<sup>24</sup>

Although stable, monomeric, paramagnetic MX<sub>3</sub>L<sub>3</sub> adducts could be isolated and characterized (ESR, X ray), the formation of diamagnetic compounds involving M–M bonding is more frequent affording di- or tetranuclear neutral adducts<sup>70</sup> or anionic trinuclear clusters. Indeed, while the TaX<sub>*n*</sub>–PR<sub>3</sub> (R = Et, Me) system offers mono- or dinuclear derivatives, the niobium system appears more prone to formation of discrete di or trinuclear anions, the counterion being derived either from the reductant (as [Mg<sub>2</sub>( $\mu$ -Cl)<sub>3</sub>(THF)<sub>6</sub>]<sup>+</sup>) or from the ligand (as the phosphonium cation HPR<sub>3</sub><sup>+</sup>). The metal is generally heptacoordinate, counting the M–M bond. Dinuclear adducts are the most common with monodentate as well as with bidentate LL donors, their formulation being M<sub>2</sub>X<sub>*n*</sub>L<sub>*n*</sub> (*n* = 3 or 4) and M<sub>2</sub>X<sub>6</sub>(LL)<sub>2</sub>, respectively. Their structure is based on confacial or edge-sharing bioctahedra (Figure 6), as also found for the anionic complex M<sub>2</sub>X<sub>9</sub><sup>3-</sup>. The short

**Figure 6** Frameworks of the dinuclear  $M^{III}$  halide adducts: (a)  $M_2X_4(\mu-X)_2(\mu-L)L_2$  ( $L = Me_2S, THT$ ); ( $X = Cl, Br, I$ ); (b) structure of  $Ta_2Cl_4(\mu-Cl)_2(PR_3)_4$

M–M distances (2.7 Å) were considered to reflect the strong metal–metal bonding of a formal double bond. Longer M–M distances ( $\approx 2.97$  Å) are found in the trinuclear monocapped clusters  $[\text{M}_3(\mu_3\text{-Cl})(\mu\text{-Cl})_3\text{Cl}_6\text{L}_3]^-$ , which have a structural unit related to that of the  $\text{Nb}_3\text{X}_8$  (X = Cl, Br, I) halides.<sup>1</sup> The solubility (in nonpolar media) and diamagnetism of the dinuclear  $\text{M}_2\text{X}_6\text{L}_n$  adducts allowed their characterization in solution by NMR ( $^1\text{H}$ ,  $^{31}\text{P}$ ). By contrast, the complexes formed with bidentate ligands are often of poor solubility. The trivalent adducts display a wide range of colors, but information on their electronic absorption spectra remains scarce.

#### 4.1.2 Reactivity of the Halide Complexes

The  $\text{M}_2\text{Cl}_6\text{L}_n$  complexes with monodentate S or P ligands were first used as starting materials. The lability of the M–S bond allowed to expand the range of  $\text{M}^{\text{III}}$  adducts, especially with bidentate donors, by ligand exchange reactions. The formation of mixed ligand adducts in which the bridging S-donor is retained suggests that the terminal ligands are more labile than the bridging ones.<sup>1,70</sup> Exploration of the reactivity of adducts based on O- or N-donors such as  $\text{NbCl}_3(\text{dme})$  or  $\text{Nb}_2\text{Cl}_6(\text{tmeda})_2$  is more recent.

Oxidative addition represents the main trend in the reactivity of the  $d^2$  complexes, either as monomers or dimers, and these compounds are thus good precursors of  $M^V$  and dinuclear  $M^{IV}$  derivatives. Oxidative reactions can occur in the course of ligand exchange reactions, such as with hydrazines<sup>2</sup> or nitriles, as well as during chlorine substitution. They are assisted by the tendency to form strong  $M=E$  multiple bonds ( $E = O, S, \text{ or } N$ ) and can lead to novel ligands either by  $C-E$  cleavage or by  $C-C$  coupling, the latter being favored by unsaturated ligands (isonitriles, nitriles, alkynes, etc.). This results in a rich inorganic and organometallic chemistry with applications in organic synthesis.<sup>22</sup>

The reaction between  $\text{Ta}_2\text{Cl}_6(\text{THT})_3$  and acetonitrile illustrates these features. It proceeds quantitatively with formation of a new bridging ligand 1,2-dimethyl-1,2-diimidoethylene, which formally derives from the coupling of two MeCN molecules (equation 22). The M–N bond distances imply an imide character.<sup>1</sup> The reaction between (43) and Na diethyldithiocarbamate provides another example of unusual reactivity with formation of a sulfide  $\text{S}^{2-}$  and a thiocarbamyl  $\text{SCN}^-\text{Et}_2$  ligand as a result of the oxidative addition of one C–S bond to the  $\text{M}^{\text{III}}$  metal (equation 23).<sup>1</sup> By contrast, similar reactions applied to  $\text{NbCl}_3(\text{dme})(\text{RC}\equiv\text{CR}')$  afforded  $\text{Nb}(\text{dtcR}'')_3(\text{RC}\equiv\text{CR}')$ .<sup>31</sup> C–S cleavage is also observed for the synthesis of thiolates from  $\text{Nb}_2\text{Cl}_6(\text{SMe}_2)_3$  (equation 24). The square  $\text{Nb}_4(\mu_4\text{-S})_2$  core of (44) is also found in  $\text{Nb}^{\text{III}}$  thiolate phosphine complexes obtained from  $\text{NbCl}_5$ .<sup>29</sup> Similar reactions applied to  $\text{TaCl}_5$  lead to  $\text{Ta}_2\text{S}_2\text{Cl}_4(\text{PR}_3)_4$ . Numerous investigations with the formamidinate  $[\text{ArNC}(\text{H})\text{NAr}]^-$  ligand have illustrated its versatility resulting in C–N cleavage with formation of arylimido  $\text{NAr}^{2-}$  or formimidoyl  $\text{HCNAr}^{3-}$  ligands, and coupling reactions.<sup>71</sup> All these reactivity patterns show the difficulty of an unequivocal formulation of the compounds in the absence of an X-ray structure.

The easy access, on a large scale, to  $\text{NbCl}_3(\text{dme})$ , by reduction of  $\text{NbCl}_5$  by tributyltin hydride, has prompted its use as a reactant in organic chemistry; it offers a convenient

route to 2-amino alcohols via the coupling of imines with aldehydes or ketones.<sup>22</sup> Other low-valent derivatives promote the stereoselective functionalization of C≡C bonds.

M<sup>III</sup> halide complexes based on mononuclear, dinuclear, tetranuclear, and hexanuclear frameworks polymerize and cyclize alkynes via different activation modes. The reactivity of the THT adducts (**43**) with alkynes RC≡CR' depends on R and R'.<sup>1</sup> A common feature is the formation of strong M–C bonds and thus of a metallacycle exhibiting properties of a metallacyclopentadiene. A manifestation of the reactivity of the coordinated alkyne as a dianionic ligand is its reductive coupling with ketones or aldehydes. Such reactions may be applicable for C–C bond formation in the synthesis of new carbonyl compounds. The Ta(OAr)<sub>3</sub> fragment provides a template for alkyne cyclotrimerization via metallacyclopentadiene and arene derivatives (*see Arene Complexes*); such reactions can provide some insight into the mechanism of the C–C coupling of alkynes (*see Niobium & Tantalum: Organometallic Chemistry*).

The dinuclear M=M chloride adducts with monodentate phosphines react cleanly with H<sub>2</sub>, Cl<sub>2</sub>, or HCl, giving dinuclear diamagnetic M<sup>IV</sup> derivatives. The oxidative addition of H<sub>2</sub> to Ta<sub>2</sub>(μ-Cl)<sub>2</sub>Cl<sub>4</sub>(PMe<sub>3</sub>)<sub>4</sub>, for instance, occurs under mild conditions, giving an air-stable dinuclear Ta<sup>IV</sup> hydride Ta<sub>2</sub>(μ-Cl)<sub>2</sub>(μ-H)<sub>2</sub>Cl<sub>4</sub>(PMe<sub>3</sub>)<sub>4</sub>. This reactivity is associated with the presence of a M=M bond and is not a general property of Nb<sup>III</sup> or Ta<sup>III</sup> derivatives. The monomeric hydride (**34**), resulting from reduction of (**32**) (equation 17) and characterized by neutron diffraction (*see Diffraction Methods in Inorganic Chemistry*), is a useful synthon in Ta<sup>III</sup> and Ta<sup>I</sup> chemistry.<sup>1</sup>

Substitution reactions generally proceed with retention of the M–M bond (*see Polynuclear Organometallic Cluster Complexes*). Trivalent compounds derived from such reactions are represented mainly by chloroalkoxides, chlorocarboxylates, carbamates, and formamidinates. A chiral, ionic Ta<sup>III</sup> compound [K(THF)<sub>6</sub>][Ta(pyt)<sub>4</sub>] (pyt = Pyridine-2-thiol) has been isolated starting from TaCl<sub>5</sub>.<sup>63</sup> The reaction between M<sub>2</sub>Cl<sub>6</sub>L<sub>3</sub> (L = THT or Me<sub>2</sub>S) and alkali carboxylates provides either dinuclear derivatives resulting from substitution or, in the case of niobium, bi-oxo-capped trinuclear clusters such as [Nb<sub>3</sub>(μ<sub>3</sub>-O)<sub>2</sub>(O<sub>2</sub>CR)<sub>6</sub>(THF)<sub>3</sub>]<sup>+</sup>. The reaction between Nb<sub>2</sub>Cl<sub>6</sub>(THT)<sub>3</sub> and inorganic aqueous acids (with exclusion of O<sub>2</sub>) has extended this class of compounds, well known in the chemistry of molybdenum and tungsten. In all compounds with a Nb<sub>3</sub>(μ<sub>3</sub>-O)<sub>2</sub> framework known presently, the number of core electrons available for Nb–Nb bonding is four, giving a bond order of 2/3 (Nb–Nb 2.84 Å *av*) (*see Metal-mediated Protein Modification*). Among these complexes, the red–brown sulfato compound, which can be obtained by reduction of Nb<sup>V</sup> in aqueous sulfuric acid, has a history that goes back to early attempts to separate and characterize niobium and tantalum; it was reported as early as 1912 but its formulation, [Nb<sub>3</sub>(μ<sub>3</sub>-O)<sub>2</sub>(μ, η<sup>2</sup>-SO<sub>4</sub>)<sub>6</sub>(H<sub>2</sub>O)<sub>3</sub>]<sup>5-</sup> (**45**), was only established by X-ray studies.<sup>9</sup> Electrochemical data on (**45**) and on the oxomethanesulfonate

analog are available.<sup>72</sup> The air-sensitive trinuclear cluster (**46**) derived from NbCl<sub>3</sub>(dme) and aqueous HCl gives, by reacting with KTp, a μ<sub>3</sub>-hydroxotrioxoborate-capped mixed-valence Nb<sup>V</sup>Nb<sub>2</sub><sup>IV</sup> cluster (**47**) (equation 25). The borate cap is lost by oxidation, thus affording the [Nb(=O)(μ-O)Tp]<sub>4</sub> species.<sup>10</sup>

NbCl<sub>3</sub>(dme) (**48**) is a useful starting material (Scheme 8). The reaction between KTp (or Tp\*) and NbCl<sub>3</sub>(dme)(PhC≡CR) (**49**) afforded an entry into Nb<sup>III</sup> trispyrazolylborate chemistry.<sup>51</sup> As for other M<sup>III</sup> alkyne species, metallocyclopropene tautomeric forms with a d°, Nb<sup>V</sup> configuration should be taken into account. An α-agostic interaction is preferred over the more common β-one due to the bulky Tp\* ligand in their alkyl derivatives. Alkyne coupling products have been obtained. Some of those derivatives polymerize ethylene at rt in the presence of B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>. NbCl<sub>3</sub>(dme) and NbCl<sub>3</sub>(dme)(PhC≡CR) were also used to form complexes of α-keto stabilized phosphorus ylides.<sup>73</sup> Ta-alkyne analogs TaCl<sub>3</sub>(RC≡CR')(LL) LL = dme, bipy, tmeda, (py)<sub>2</sub> have only become available recently.<sup>74</sup>

## 4.2 Reactivity of d<sup>2</sup> Derivatives Supported by Ligands other than Halogens

The monomeric M<sup>III</sup> centers supported by bulky O-donors such as siloxide or aryloxide are extremely effective in reduction, cleaving numerous C–E bonds (E = O, S, halides, etc.), and exhibit unusual coordination behavior. A manifestation of the electrophilic behavior of Ta(silox)<sub>3</sub> (**51**) is its cleavage of CO (equation 26), giving an oxo derivative and a dinuclear carbide (**53**). The reducing power of (**52**) is also illustrated in the unusual coordination found for both pyridine and benzene. In coordination to these aromatics in a η<sup>2</sup> fashion (η<sup>2</sup>-N,C for pyridine as shown in Figure 7), the metal can achieve its highest formal oxidation state. X-ray as well as NMR data indicate an interruption of the heterocycle π-system.<sup>22,23</sup> The nucleophilic attack on a similar η<sup>2</sup>-N,C coordinated pyridine supported by a Ta aryloxide fragment led to a regioselective C–N bond cleavage, providing models for hydrodenitrogenation (HDN).<sup>22</sup> Oxygen vs sulfur ligation for the ancillary ligands has been discussed.<sup>75</sup> Nb(silox)<sub>3</sub>(PMe<sub>3</sub>) (**54**), a masked Nb<sup>III</sup> species, promoted ring

**Scheme 8** Reactivity of Nb<sup>III</sup> dme halide adducts

**Figure 7** The unusual  $\eta^2$ -N,C coordination mode for pyridine in Ta(silox)<sub>3</sub>(pyridine)

opening of 3,5-lutidine with participation (cyclometallation) of a silox ligand, a rare example for this typically ancillary ligand.<sup>76</sup> Although desoxygenation of small molecules such as CO or NO (**52**) is very fast, (**54**) was more effective for desoxygenation of OPR<sub>3</sub> (R = Me, Ph) giving MO(silox)<sub>3</sub>.<sup>23</sup>

As already mentioned, stepwise cleavage of the N≡N bond was assisted by the very reactive Nb=Nb unit (2.659 Å) of a Nb<sup>III</sup>-calix[4]arene.<sup>45</sup> A 4e reduction gives a Nb<sup>IV</sup> complex

with a bridging hydrazido N<sub>2</sub><sup>4-</sup> anion [Nb≡N 1.747 Å, N–N 1.390 Å], further 2e reduction using Na lead to a nitride.

## 5 CLUSTERS WITH NONINTEGRAL OXIDATION STATES

The chemistry of reduced Nb and Ta halides is rich in clusters with various structures. The metal atoms assemble with metal–metal distances close to those in the metal into triangular and tetranuclear clusters but the dominant structural motif is that of the octahedral M<sub>6</sub>X<sub>12</sub> and Nb<sub>6</sub>I<sub>8</sub> types.<sup>1,2</sup> Binary, ternary, and quaternary compounds all crystallize in that type. The M<sub>6</sub> clusters are characteristic of the chemistry of the lower oxidation states of Nb and Ta, although not restricted to them. These electron-deficient clusters are based on metal ions with average oxidation numbers between III and I.

The trinuclear clusters derive formally from the M<sub>3</sub>X<sub>8</sub> halides, which remain unknown for tantalum.<sup>1</sup> Coordination compounds whose structure is related to that of these halides are represented by tetranuclear clusters such as the Nb<sub>4</sub>Cl<sub>10</sub>(PMe<sub>3</sub>)<sub>6</sub> complex, the CsNb<sub>4</sub>Cl<sub>11</sub> subhalide,<sup>1</sup> or the mixed–valence Nb<sub>2</sub><sup>II</sup>Nb<sub>2</sub><sup>III</sup>Cl<sub>12</sub>Li<sub>2</sub>(THF)<sub>8</sub> (**37**) cluster.<sup>77</sup> Their structure consists of Nb<sub>3</sub> units fused into a centrosymmetric rhombus with the capping μ<sub>3</sub>-ligands on opposite sides and a planar Nb<sub>4</sub> arrangement (Figure 8).<sup>1</sup> Trimetallic halide cations stabilized by hexamethylbenzene have been obtained by Friedel–Crafts reductive synthesis.<sup>1</sup> Similar frameworks have been observed for oxo Cp\*Nb derivatives obtained by reductive aggregation, although their metal oxidation state is higher (Nb<sub>3</sub><sup>13+</sup> core).

**Figure 8** Assembly of trinuclear monocapped units into tetranuclear frameworks: the structure of  $\text{Nb}_4\text{Cl}_{10}(\text{PMe}_3)_4$

The lowest halides obtained under strongly reducing conditions, often in aqueous media, or by thermal disproportionation of the higher halides, correspond mostly to the compositions  $\text{M}_6\text{X}_{15}$  ( $\text{M} = \text{Nb}$ ,  $\text{X} = \text{F}$ ;  $\text{M} = \text{Ta}$ ,  $\text{X} = \text{Cl}$ ,  $\text{Br}$ ,  $\text{I}$ ),  $\text{M}_6\text{X}_{14}$  ( $\text{M} = \text{Nb}$ ,  $\text{X} = \text{Cl}$ ,  $\text{Br}$ ;  $\text{M} = \text{Ta}$ ,  $\text{X} = \text{Br}$ ,  $\text{I}$ ), and  $\text{Nb}_6\text{I}_{11}$ . These high-electron density metal complexes are either insulators or semiconductors<sup>78</sup> and have attracted attention recently for their potential as X-ray contrasting agents.<sup>79</sup> They are actually built up of two types of octahedral clusters;  $[\text{M}_6\text{X}_{12}]^{q+}$  ( $q = 2-4$ ) units can be described as  $\text{M}_6$  clusters whose edges are capped by 12 ‘inner’ (bridging) ligands  $\text{X}^i$  and, in addition, six ‘outer’ or ‘centrifugal’ ligands  $\text{X}^a$  occupy the pseudo quaternary axes of the  $\text{M}_6$  core (Figure 9a), thus leading to the general formula  $[\text{M}_6\text{X}_{12}^i]\text{X}_6^a$ . The  $[\text{M}_6\text{X}_8]^{q+}$  ( $q = 2, 3$ ) cluster is built up of an  $\text{M}_6$  core whose faces are capped by eight inner ( $\mu_3$ -) ligands and six outer ligands (Figure 9b). Since these compounds can be obtained in aqueous media, their discovery is old, but their correct formulation had to await modern structural X-ray methods.  $[\text{Ta}_6\text{Cl}_{14}] \cdot 8\text{H}_2\text{O}$ , the first subhalide hydrate, was prepared as early as 1907, but it was formulated as  $\text{TaCl}_2 \cdot 2\text{H}_2\text{O}$ .

The fast and quantitative *Disproportionation* of Nb or Ta with their pentahalides in the presence of an alkali halide has long been used. This synthesis is assisted by the stabilization of the cluster through complexation with the  $[\text{M}_6\text{X}_{18}]^{4-}$  anion. The relative stabilities of the other possible clusters depend on the alkali metal.<sup>1</sup> Replacement of the group V metals as reductant by gallium or  $\text{Ga}_2\text{Cl}_4$  (actually  $\text{Ga}^+ \text{GaCl}_4^-$ ) has afforded a convenient, cheap, lower temperature route to the  $[\text{M}_6\text{X}_{12}]^{2+} \text{X} = \text{Cl}, \text{Br}$  core.<sup>79</sup>

$[\text{Nb}_6\text{X}_{12}]^{q+}$  and  $[\text{Ta}_6\text{X}_{12}]^{q+}$  clusters are redox-promiscuous possessing five ( $q = 1-5$ ) and four ( $q = 1-4$ ) accessible oxidation states respectively. Disproportionation reactions therefore complicate ligand-substitution chemistry. The hydrates, being more soluble than the anhydrous lower halides, are useful starting materials. The high lability of the ‘centrifugal’ ligands allows access to mixed halides, hydrates,

**Figure 9** Octahedral clusters: (a) the  $[\text{M}_6\text{X}_{12}]^{q+}$  core with additional centrifugal ligands L; (b) the  $[\text{M}_6\text{X}_8]^{q+}$  core

and oxygen; nitrogen or phosphorus donors complexes of the form  $[(\text{M}_6\text{X}_{12}^i)\text{X}_{6-x}^a\text{L}_x]^{(q-x)+}$  with  $\text{X}^i = \text{Cl}, \text{Br}$ ,  $\text{X}^a = \text{halide}$ ,  $\text{CN}$ ,  $\text{OSO}_2\text{CF}_3$ ,  $\text{OH}$ ,  $\text{BF}_4$ ,  $\text{OMe}$ , and  $\text{L} = \text{H}_2\text{O}$ ,  $\text{DMSO}$ ,  $\text{DMF}$ ,  $\text{OPPh}_3$ ,  $\text{OAsPh}_3$ ,  $\text{NH}_3$ ,  $\text{MeCN}$ ,  $\text{pyridine}$ ,  $\text{PR}_3$ . The stability of  $[\text{M}_6\text{X}_{12}]^{q+}$  compounds toward hydrolysis decreases in the order  $\text{Ta} > \text{Nb}$ ,  $\text{Cl} > \text{Br}$ , and with increasing oxidation states. Moisture- and oxygen-sensitive alkoxides of  $\text{M}_6$  units have been obtained by substitution reactions; their hydrolysis offers a clean route to cluster hydroxides.<sup>78</sup>

The preparation of pure  $[\text{M}_6\text{X}_{12}]^{2+}$  complexes from aqueous solutions is not easy, as oxidation to  $[\text{M}_6\text{X}_{12}]^{3+}$  occurs with air. Oxidation is slow in neutral solution, but fast in acidic or basic media. The presence of  $[\text{M}_6\text{X}_{12}]^{3+}$  may be detected by a band in the UV-vis spectra near  $8000 \text{ cm}^{-1}$ . Addition of reductants ( $\text{SnCl}_2$  or  $\text{Cd}$ ) to oxidized solutions allows a return of the green color of the  $[\text{M}_6\text{X}_{12}]^{2+}$  clusters. In the solid state,  $\text{Ta}_6\text{Cl}_{14} \cdot 8\text{H}_2\text{O}$  undergoes reversible oxidation by *Topotactic* electron-proton transfer. While oxidation under mild conditions (iodine) leads to the paramagnetic yellow  $[\text{M}_6\text{X}_{12}]^{3+}$  clusters, two or more moles of strong oxidants ( $\text{H}_2\text{O}_2$ ,  $\text{Ce}^{\text{IV}}$ ) led to the red-brown diamagnetic  $[\text{M}_6\text{X}_{12}]^{4+}$

(X = Cl, Br) derivatives. Oxidation is faster for the chloride than for the bromide clusters. No redox chemistry has yet been reported for the fluoride or iodide clusters. Spontaneous reduction is observed for all  $[M_6X_{12}]^{4+}$  clusters, except  $[Ta_6Br_{12}]^{4+}$ , upon redissolution. Examples of reduction by ligands appear limited to that of  $Nb_6Cl_{15} \cdot 7H_2O$  by phosphines to give  $(Nb_6Cl_{12})Cl_2(PR_3)_4$ . Its cyclic voltammetry in nonaqueous media revealed three monoelectronic reductions (see *Electrochemistry: Applications in Inorganic Chemistry*). The stabilizing effect of  $PR_3$  leads to a redox chemistry that is more extensive than that in aqueous media. Indeed the monoanions  $[(M_6Cl_{12})Cl_2(PR_3)_4]^-$  (**55**), formally derived from the previously unknown  $[M_6X_{12}]^{4+}$  core, are detected; attempts to synthesize them have failed so far. The average oxidation state of the metal in (**55**) remains higher than for  $[Nb_6I_8]^{2+}$ . The  $[M_6X_{12}]^{q+}$  clusters displaying several oxidation states with small differences in redox potentials are attractive candidates for multielectron transfer reactions. In addition, the delocalization of the redox orbitals over the clusters might reduce their sensitivity to decomposition. Irradiation (see *Photochemistry of Transition Metal Complexes*) of  $[Ta_6Br_{12}]^{2+}$  in oxygen-free HCl solution led to  $[Ta_6Br_{12}]^{3+}$  and  $H_2$ . An application of these clusters is their intercalation and subsequent oxidation to metal oxide aggregates in pillared clays such as montmorillonite<sup>1</sup> (see *Intercalation Chemistry*).

$[M_6X_{12}]^{q+}$  clusters have been studied by X-ray diffraction, far-IR, UV-vis, XPS, and NQR.<sup>1</sup> The influence of the oxidation state on their structures can be evaluated from comparison of the X-ray data. The regular octahedral symmetry usually considered for the isolated clusters is an oversimplified view and five structural types can be distinguished. A contraction of the M–M bonds is observed upon increase of the number of valence electrons on the metal available for M–M bonding (valence electron count or VEC).<sup>78</sup> The Nb–Nb intracuster distances increase from 2.91, to 2.97, and 3.02 Å when the VEC decreases. The M–M stretching vibration in the IR has been located around 140 cm<sup>−1</sup> or in the 60–110 cm<sup>−1</sup> range. DFT calculations provide a better description of the relationships between the structural arrangement and the number of valence electron count (VEC) than extended hückel molecular orbital (EHMO) calculations. The observation that both the  $[M_6X_{12}]^{2+}$  (16e) and  $[M_6X_{12}]^{4+}$  (14e) clusters are diamagnetic and the values of the magnetic moments (see *Magnetism of Transition Metal Ions*) found for the  $[M_6X_{12}]^{3+}$  clusters show that the 15th and 16th electrons occupy a nondegenerate molecular orbital. A compilation of visible spectra on the solid state or in solution is available.<sup>1</sup>

A growing chemistry of niobium oxide clusters continues to emerge.<sup>78</sup> The reduced niobates and the NbO suboxide are also built up from condensation of  $M_6$  units through shared vertices, namely,  $Nb_6O_{12}$ . Although the inner halides within the  $[M_6X_{12}]^{q+}$  core are relatively inert to substitution,  $Nb_6$  and  $Ta_6$  oxohalides, such as  $[Nb_6Cl_{12-m}O_m]^{n+}$  ( $m = 1-4$ ) and

even  $Nb_6$  oxohydroxohalides, could be obtained by excision reactions.<sup>80</sup> Oxyhalide  $A_xLnM_6X_{18-x}O_x$  compounds containing paramagnetic as well as nonparamagnetic lanthanide cations could also be prepared.

The  $Rb_3[Nb_6SBr_{17}]$  salt is the first example of an isolated trigonal-prismatic  $Nb_6$  cluster. The  $Nb_6$  units (distortion of structure of Figure 9(a)) enclosing an interstitial sulfide are linked through two terminal bromine.<sup>78</sup>

$Nb_6I_{11}$  (**56**) and  $Nb_6I_9S$  are the lowest subhalides reported so far for niobium and tantalum. The structure of  $Nb_6I_{11}$  is atypical, since it is based on a  $[Nb_6I_8]^{3+}$  unit and can be written as  $[Nb_6I_8]I_{6/2}$ . The  $[Nb_6I_8]^{3+}$  moiety is paramagnetic and above 300 °C (**56**) absorbs  $H_2$ , giving diamagnetic  $Nb_6I_{11}H$ , where the hydrogen occupies the center of the  $Nb_6$  cluster, as shown by neutron diffraction. A discrete complex possessing the  $[Nb_6I_8]^0$  core,  $Nb_6I_8(NH_2Me)_6$ , was obtained by reacting (**56**) with the amine in ethanol.<sup>1,78</sup> Unlike  $Nb_6I_{11}$  and related compounds, it does not form an extended lattice. It represents the lowest oxidation state yet observed in a  $Nb_6$  cluster.

## 6 MOLECULAR COMPOUNDS IN OXIDATION STATES II AND LOWER

The number of niobium and tantalum coordination compounds in oxidation states lower than II is limited, and they often are organometallic derivatives involving carbonyl, cyclopentadienyl, or alkenic ligands.

The first member of the series where the metal has a  $d^3$  configuration,  $TaCl_2(dmpe)_2$ , was reported in 1977. Mononuclear paramagnetic halide adducts such as  $MX_2(PMe_3)_4$  and  $MCl_2(dmpe)_2$  have been isolated by reduction of monomeric  $M^V$  or  $M^{IV}$  phosphine complexes.  $TaCl_2(PMe_3)_4$  opens up access to  $Ta^{IV}$  and  $Ta^{III}$  chlorohydrides.<sup>1</sup> The niobium aryloxide (**57**), whose structure is related to that of  $TaCl_2(dmpe)_2$ , gives, by oxidation by the parent phenol, an ionic mixed-valence species (**58**) (equation 27). Monomeric  $t-NbCl_2(py)_4$  is easily accessible by reduction of (**29**) (Scheme 7).<sup>63</sup> Reduction of  $TaCl_5$  in similar condition gave a  $Ta^{III}$  species.

Species with  $M \equiv M$  triple bonds are recent. Although dinuclear  $M^{II}$  species such as  $Cp_2Nb_2L_4(\mu-Cl)_2$  ( $L = CO, RC \equiv CR'$ ) were known, their Nb–Nb distance is that of a single bond. The synthesis of  $TaCl_2(PMe_3)_4$  requires excess of  $PMe_3$  in order to preclude the formation of the  $M \equiv M$  bonded dimers  $Ta_2Cl_6(PMe_3)_4$  that cannot be reduced by

afforded the  $M(\text{PF}_3)_6\text{H}$  hydrides, the Nb one being quite unstable.<sup>85</sup>

Two-electron transfer processes applied to the hexacarbonyl  $[\text{M}(\text{CO})_6]^-$  (38) anions using reactants such as hydric acids, nickel acetylacetonate, or metal halides offered  $[\text{M}_2\text{Cl}_3(\text{CO})_8]^-$ , the first halocarbonyl complexes without ancillary ligands (see *Ancillary Ligand*), or the  $\beta$ -diketonate  $\text{Ta}(\text{acac})(\text{CO})_4(\text{THF})$ .<sup>1,22</sup> The cothermolysis of  $\text{Cp}''\text{Ta}(\text{CO})_4$  ( $\text{Cp}'' = 1,3\text{-}t\text{Bu}_2\text{C}_5\text{H}_3$ ) with  $\text{As}_4$  or  $(\text{RAs})_n$  afforded polynuclear Ta derivatives with  $\text{As}_n$  moieties ( $n = 3, 6$  or  $8$ ) as ligands. The phosphido-phosphinidene coordination mode of a  $\text{P}_2$  ligand has been realized in the trinuclear complex  $(\text{Cp}''\text{Ta})_3(\text{P}_4)(\text{P}_2)$  obtained by thermolysis of  $\text{Cp}''\text{Ta}(\text{CO})_4$  and  $\text{P}_4$ .<sup>86</sup>

Metal vapor synthesis techniques (see *Metal Vapor Synthesis of Transition Metal Compounds*) are the most convenient access to  $\text{M}^0$  derivatives, solution routes being limited to the synthesis  $\text{Nb}(\text{Mes})_2$ .<sup>5</sup> Highly air-sensitive, paramagnetic but crystalline  $\text{M}(\text{dmpe})_3$  with a distorted octahedral geometry were isolated in good yields. The formally zerovalent  $17e$   $\text{M}(\text{iPr}_2\text{dad})_3$  species were shown by *DFT calculations* to be actually  $[\text{Ta}]^+[(\text{iPr}_2\text{dad})_3]^-$  rather than  $\text{Ta}^0$  species.<sup>84</sup> The  $17e$  species,  $\text{Ta}(\text{CO})_4(\text{dppe})$ , has been the first  $\text{Ta}^0$  carbonyl isolated. The first nitrosyl complexes of Nb and Ta were reported in 1998.<sup>87</sup> They were obtained in high yields according to equation (30). Diazald (*N*-methyl-*N*-nitroso-*p*-toluenesulfonamide) was the source of the nitrosyl. The  $\text{M}-\text{N}$  bond distances suggest multiple  $\text{M}-\text{N}$  bonding due to  $\text{M} \rightarrow \text{NO}$  back bonding.

$[\text{Nb}(\text{CO})_6]^-$  (38) has become accessible in high yield by reduction of  $\text{NbCl}_4(\text{THF})_2$  at atmospheric pressure (Scheme 7).<sup>85</sup>  $[\text{Nb}(\text{PF}_3)_6]^-$  is accessible either by photolysis (see *Photosynthesis*) of  $[\text{Nb}(\text{CO})_6]^-$  under  $\text{PF}_3$  or by a reductive route similar to that of (38). The  $^{93}\text{Nb}$  NMR chemical shifts suggest weaker  $\text{Nb}-\text{PF}_3$  bonds than  $\text{Nb}-\text{CO}$  ones.<sup>1</sup>

No derivative in which niobium or tantalum displays an oxidation state of  $-II$  has been reported so far, while carbonyl complexes derived from  $[\text{M}(\text{CO})_5]^{3-}$  represent the only coordination compounds for these metals in oxidation state  $-III$ .

## 1 INTRODUCTION

Organometallic chemistry of niobium and tantalum has developed rapidly over the past ten years, as judged by the number of papers published in the field. This review covers the literature between 1993 to early 2003. *SciFinder (Chemical Abstracts)* searches were conducted on “niobium (Nb) or tantalum (Ta)” between 1993 and early 2003. The hits were then sorted so that those in Section 29 (Organometallic and Organometalloidal Compounds) were selected. In addition, hits in Sections 78 (Inorganic Chemicals and Reactions) and 67 (Catalysis, Reaction Kinetics, and Inorganic Reaction Mechanisms) were also reviewed. This paper is primarily based on the literature from these searches. Because of the limit of space, the current paper highlights leading literature during this period. General references for niobium and tantalum organometallic chemistry include the chapter by Wigley and Gray in *Comprehensive Organometallic Chemistry II*, which reviews the literature through 1993.<sup>1</sup> M refers to Nb and Ta throughout this chapter.

## 2 CARBONYLS, ISOCYANIDES, PHOSPHAALKYNES, AND AZIDES

### 2.1 Carbonyls and Substituted Carbonyls

#### 2.1.1 Carbonyl Complexes without Cyclopentadienyl Ligands

Unlike stable V(CO)<sub>6</sub>, neutral M(CO)<sub>6</sub> (M = Ta, Nb) have not been characterized (except in matrix-isolation experiments,<sup>2</sup> see *Matrix Isolation*). Neutral mixed-ligand complexes were unknown until 1996. The first Ta(0) carbonyl complex Ta(CO)<sub>4</sub>(dppe) was synthesized by the reaction of hydride TaH(CO)<sub>4</sub>(dppe) with the (*p*-Bu<sup>t</sup>C<sub>6</sub>H<sub>4</sub>)<sub>3</sub>C• radical.<sup>3</sup> This complex exists as a CO-bridged dimer in solid and, in solution, as an equilibrium mixture of the monomer and dimer.<sup>4</sup>

Density functional theory calculations of 17-electron (see *Seventeen Electron Configuration*), metal-centered radical Ta(CO)<sub>6</sub> and its dimer [Ta(CO)<sub>6</sub>]<sub>2</sub> show that the dimer is energetically bound with respect to the monomer. The bidentate phosphine ligand in Ta(CO)<sub>4</sub>(H<sub>2</sub>PCH<sub>2</sub>CH<sub>2</sub>PH<sub>2</sub>) leads to several energetically competitive chelated dimers. In these dimers, linear semibridging carbonyls (see *Semibridging Carbonyl Ligand*) support a weak, delocalized Ta–Ta interaction.<sup>5</sup>

A recent review gives a chronological survey of the syntheses and characterizations of homoleptic mononuclear metal-carbonyl (see *Carbonyl Complexes of the Transition Metals*) anions.<sup>6</sup> [M(CO)<sub>6</sub>]<sup>−</sup> is a key precursor to niobium and tantalum carbonyls. More reliable synthesis of [Ta(CO)<sub>6</sub>]<sup>−</sup><sup>7</sup>

and a higher yield route to  $[\text{Nb}(\text{CO})_6]^-$ <sup>8</sup> are now available. Reduction of  $[\text{Nb}(\text{CO})_6]^-$  by sodium in liquid ammonia affords  $[\text{Nb}(\text{CO})_5]^{3-}$ , the only known  $\text{Nb}^{3-}$  species.<sup>8</sup> Treatment of  $[\text{Et}_4\text{N}][\text{M}(\text{CO})_6]$  with  $\text{I}_2$  produces  $[\text{M}_2(\mu-\text{I})_3(\text{CO})_8]^-$ . Addition of trimpesi [trimpesi =  $\text{Bu}^t\text{Si}(\text{CH}_2\text{PMe}_2)_3$ ] to  $[\text{M}_2(\mu-\text{I})_3(\text{CO})_8]^-$  affords (trimpesi) $\text{M}(\text{CO})_3\text{I}$  (**1**). Treatment of (**1**) with  $\text{Na}/\text{Hg}$  followed by diazald results in the formation of (trimpesi) $\text{M}(\text{CO})_2(\text{NO})$ , the first nitrosyl complexes of niobium and tantalum.<sup>9</sup>

Vibronic structure and coupling (*see Vibronic Coupling*) in the electronic spectra of  $[\text{Ph}_4\text{P}][\text{Ta}(\text{CO})_6]$  have been studied. The emission spectrum originates from a ligand field transition. There is an apparent energy gap between the red and the blue regions of the spectrum, and this is interpreted in terms of Herzberg–Teller coupling of the ligand field state, with an allowed Ta-to-CO charge-transfer (*see Charge Transfer*) excited state.<sup>10</sup>

### 2.1.2 Cyclopentadienyl Carbonyl Complexes

The cyclopentadienyl carbonyl derivatives  $(\text{C}_5\text{R}_5)\text{M}(\text{CO})_4$  are easily prepared by reductive carbonylation (*see Reductive Carbonylation*) of  $(\text{C}_5\text{R}_5)\text{MCl}_4$  under CO.  $[\text{M}_2(\mu-\text{Cl})_3(\text{CO})_8]^-$  readily reacts with  $\text{NaC}_5\text{H}_4\text{R}$  to give  $(\text{C}_5\text{H}_4\text{R})\text{M}(\text{CO})_4$ .<sup>11</sup> Reduction of the borolide complex  $\text{Cp}^*[\text{C}_4\text{H}_4\text{B-NPr}^i_2]\text{TaCl}_2$  with Mg under CO gives  $\text{Cp}^*[\text{C}_4\text{H}_4\text{B-NPr}^i_2]\text{Ta}(\text{CO})_2$ .<sup>12</sup> Carbonylation of  $\text{CpTa}(\eta^4\text{-butadiene})(\eta^2\text{-C}_2\text{H}_4)(\text{PMe}_3)$  afforded monocarbonyl  $\text{CpTa}(\eta^4\text{-butadiene})(\text{CO})(\text{PMe}_3)$  and dicarbonyl  $\text{CpTa}(\eta^4\text{-butadiene})(\text{CO})_2$ .<sup>13</sup>

Gas-phase photoelectron spectroscopy has been used to study the bonding in  $\text{CpM}(\text{CO})_4$ ,  $\text{Cp}'\text{M}(\text{CO})_4$ , and  $(\eta^5\text{-C}_5\text{H}_4\text{COMe})\text{Nb}(\text{CO})_4$ . The character of two overlapping ionizations in the lowest ionization energy region is dominated by the carbonyls rather than by the metals. The second group of ionizations corresponds to orbitals with predominantly cyclopentadienyl  $\pi$  character that donate to empty metal d orbitals. A much larger shift of these ionizations is observed upon cyclopentadienyl substitution.<sup>14</sup>

$\mu$ -Phosphido complex  $\text{Cp}''\text{CpTa}(\mu\text{-CO})(\mu\text{-PMe}_2)\text{W}(\text{CO})_4$  ( $\text{Cp}'' = 1\text{-Bu}^t\text{-3,4-Me}_2\text{-C}_5\text{H}_2$ ) reacts with an optically active phosphine ( $\text{PRR}'\text{R}''$ ) to give a pair of optically active diastereoisomers  $\text{Cp}''\text{CpTa}(\text{CO})(\mu\text{-PMe}_2)\text{W}(\text{CO})_4(\text{PRR}'\text{R}'')$ . X-ray structure determinations of these diastereoisomers lead to the assignment of absolute configurations of the Ta chiral centers.<sup>15</sup>

### 2.2 CO Reductive Coupling

The reductive coupling (*see Reductive Coupling*) of CO ligands in  $\text{M}(\text{CO})_2(\text{dmpe})_2\text{Cl}$  ( $\text{M} = \text{V}$ ,  $\text{Nb}$ , or  $\text{Ta}$ ) to form  $\text{M}(\text{R}_3\text{SiOC}\equiv\text{COSiR}_3)(\text{dmpe})_2\text{X}$  occurs via sequential formation of  $\text{Na}[\text{M}(\text{CO})_2(\text{dmpe})_2]$  and  $\text{M}(\equiv\text{COSiR}_3)(\text{CO})(\text{dmpe})_2$  complexes. Reactions of siloxy-carbynes (*see Carbyne Complexes*)  $\text{M}(\equiv\text{COSiR}_3)(\text{CO})$

$(\text{dmpe})_2$  ( $\text{R}_3 = \text{Pr}^i_3$ , **2a**;  $\text{Bu}^t\text{Ph}_2$ , **2b**;  $\text{Ph}_3$ , **2c**) with, for example,  $\text{Me}_3\text{SiCl}$  afford CO reductive coupling products  $\text{Ta}(\text{R}_3\text{SiOC}\equiv\text{COSiMe}_3)(\text{dmpe})_2\text{Cl}$ . Kinetic studies of carbyne/CO coupling in the reaction of  $\text{Ta}(\equiv\text{COSiPr}^i_3)(\text{CO})-(\text{dmpe})_2$  with  $\text{Me}_3\text{SiCl}$  to form  $\text{Ta}(\text{Me}_3\text{SiOC}\equiv\text{COSiPr}^i_3)(\text{dmpe})_2\text{Cl}$  show that the reaction is first order in both the Ta complex and  $\text{Me}_3\text{SiCl}$  in the presence of excess  $\text{Bu}^n_4\text{NBPh}_4$ , suggesting that initial electrophilic attack of the silyl reagent occurs at the O atom of the carbonyl ligand.<sup>16,17</sup> Reactions of carbon-based electrophiles (e.g.  $\text{AcCl}$ ) with the siloxycarbynes such as (**2b**) and  $\text{M}(\text{COSiBu}^t\text{Ph}_2)(\text{CO})(\text{depe})_2$  give mixed siloxy/alkoxyacetylene complexes  $\text{M}(\text{Ph}_2\text{Bu}^t\text{SiOC}\equiv\text{COAc})-(\text{P}_2)_2\text{Cl}$  ( $\text{P}_2 = \text{dmpe}$ ,  $\text{depe}$ ).<sup>18</sup> Similarly,  $\text{AcCl}$  reacts with  $\text{Na}[\text{Ta}(\text{CO})_2(\text{P}_2)_2]$  to yield  $\text{Ta}(\text{AcOC}\equiv\text{COAc})(\text{P}_2)_2\text{Cl}$  through direct alkylation at the terminal CO ligands.<sup>18</sup> Treatment of methylene  $\text{Cp}_2\text{Ta}(\text{=CH}_2)\text{Me}$  with carbonyls  $\text{Co}_2(\text{CO})_8$  and  $\text{Fe}_2(\text{CO})_9$  results in CO coupling reactions to yield trinuclear complexes (**3**).<sup>19,20</sup>

(**3**)  $\text{M} = \text{Co}$ ,  $x = 3$   
 $\text{M} = \text{Fe}$ ,  $x = 4$

Reaction of  $\text{Cp}^*\text{TaMe}_2(\text{=NXyl})$  with CO gives an ene diolate  $[\text{Cp}^*\text{Ta}(\text{=NXyl})\text{Me}]_2\{\mu\text{-}\eta^2\text{-OC}(\text{Me})=\text{C}(\text{Me})\text{O}\}$  via intermolecular coupling between acyls of an intermediate  $\text{Cp}^*\text{TaMe}\{\text{=NXyl}\}\{\eta^2\text{-C}(\text{Me})=\text{O}\}$  (**4**).<sup>21,22</sup> In comparison, the reaction of the chloro analog  $\text{Cp}^*\text{TaMeCl}(\text{=NXyl})$  with CO yields an unexpected oxo  $\eta^2$ -iminoacyl complex  $\text{Cp}^*\text{TaCl}(\text{O})[\eta^2\text{-C}(\text{Me})=\text{NXyl}]$  through an intermediate  $\text{Cp}^*\text{TaCl}(\text{=NXyl})[\eta^2\text{-C}(\text{Me})=\text{O}]$ .<sup>21</sup>

Similar coupling reactions were observed when  $[\text{Ta}(\text{OEP})\text{Me}_2](\text{BPh}_4)$  ( $\text{OEP} = \text{octaethylporphyrin}$ ) and a bis (amidinate) complex  $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{TaMe}_3$  were added CO to give  $\{\text{Ta}(\text{OEP})[\text{OC}(\text{Me})=\text{CMe}(\text{O})]\}(\text{BPh}_4)$ ,<sup>23</sup> and  $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{Ta}[\text{OC}(\text{Me})=\text{C}(\text{Me})\text{O}]\text{Me}$ ,<sup>24</sup> respectively.

### 2.3 Complexes of Isocyanides, Phosphaalkynes, Azides, and the Reductive Coupling of the Ligands

The interests in homoleptic (*see Homoleptic Compound*) isocyanide ('isonitrile,' *see Isocyanide Ligands*) complexes of transition metals have largely been associated with their similarities to metal carbonyls. The greater versatility of isocyanide ligands in comparison to CO makes isocyanide complexes potentially valuable reagents in synthetic chemistry and catalysis. The dication  $[\text{V}(\text{CNBu}^t)_6]^{2+}$  reported in 1980 remained the sole example of a homoleptic group 5 metal isocyanide until 1999, when the first binary

Nb and Ta isocyanides were isolated.<sup>25</sup> Two-electron oxidation of anions  $[M(CO)_6]^-$  by  $AgBF_4$  in the presence of  $CNXyl$  and a mixture of  $CNXyl$  and  $I_2$  yields  $[M(CNXyl)_7](BF_4)$  and  $MI(CNXyl)_6$ , respectively.<sup>25</sup> Direct reactions of  $[M(CO)_6]^-$  with  $CNR$  and  $X_2$  also yield halo isocyanide complexes such as  $[I_2M^{III}(CNBu')_6]I$  and  $ITa(CO)_3(CNBu')_3$ . In the presence of a small amount of water, the reaction of  $[Nb(CO)_6]^-$  gives aminoalkyne complexes  $[X_2Nb(CNBu')_4(Bu'HNC\equiv CNHBu')]X$  ( $X = I, Br$ ), suggesting successive protonation and intramolecular reductive isocyanide coupling (see *Reductive Coupling*) mediated by a  $Nb^I$  center.<sup>26</sup> Direct nitrosylation of  $[M(CO)_6]^-$  with  $(NO)^+$  in the presence of  $CNXyl$  yields *cis*- $[M(NO)_2(CNXyl)_4]^+$ , the first dinitrosyls of niobium and tantalum.<sup>27</sup>

In the reactions of dibenzyl 1-aza-1,3-butadiene complexes (5) with  $CNXyl$ , alkyl-insertion followed by coupling with the 1-aza-1,3-butadiene ligand affords amido-imido complexes (6).<sup>28</sup> The reaction of  $Cp^*TaMe_2(SCH_2CH_2)_2O$  with  $CNXyl$  yields  $Cp^*Ta(\eta^2-XylNCMe_2)(SCH_2CH_2)_2O$ , which undergoes a second isocyanide insertion to yield (7).<sup>29</sup> A similar reaction of  $Cp^*TaMe_3(SC_6H_7N_2)$  with  $CNXyl$  gives (8).<sup>30</sup>

The Ta hydride compound  $Ta(OAr)_2Cl_2(H)(PMe_2Ph)_2$  ( $Ar = 2,6-Pr^i_2-C_6H_3$ , **9**) reacts with  $RNC$  ( $R = Xyl, 2,6-Pr^i_2-C_6H_3$ ) to yield the ylide (see *Ylide*) derivatives (10a). The reaction of (9) with  $Bu'NC$  gives the keteneimine complex (10b).<sup>31</sup>

$Cp_2Ta(=CH_2)Me$  reacts with 1 and 2 equiv of  $HB(C_6F_5)_2$  to give  $Cp_2Ta[CH_2B(C_6F_5)_2](\mu-H)Me$  (11) and  $Cp_2Ta[CH_2B(C_6F_5)_2](\mu-H)(H)$ , respectively. Reductive elimination (see *Reductive Elimination*) of  $CH_4$  from (11) in the presence of  $Bu'NC$  (or  $CO$ ) and  $R'NC$  ( $R' = Cy, PhCH_2$ ) leads to the formation of  $Cp_2Ta^{III}[\eta^2-CH_2B(C_6F_5)_2](L)$  ( $L =$

$Bu'NC, CO$ ),<sup>32</sup> and unusual  $\eta^3$ -1-azaallyl  $Ta^{III}$  complexes (12).<sup>33</sup>

Substitution of  $CO$  ligands in  $Cp^*TaCl_2(CO)_2(THF)$  with phosphalkynes  $RC\equiv P$  ( $R = Bu', adamantyl$ ) gives  $\eta^2(4e)$ -bonded  $Cp^*TaCl_2(P\equiv CR)$ . Treating  $Cp^*TaCl_2(P\equiv CBu')$  with additional  $P\equiv CBu'$  gives the 1,2-diphosphacyclobutadiene complex (13).<sup>34</sup>

Aryl azides  $ArN_3$  ( $Ar = Ph, p-CF_3C_6H_4, p-Me_2NC_6H_4$ ) replace  $PMe_3$  in  $Cp_2TaMe(PMe_3)$ , affording rare examples of terminal phenylazido complexes  $Cp_2TaMe(N_3Ar)$ , which under heating or UV irradiation give imides  $Cp_2TaMe(=NAr)$  and  $N_2$ . Thermolysis of  $Cp_2TaMe(NN^{15}NPh)$  yields  $Cp_2TaMe(^{15}NPh)$ . Crossover (see *Crossover Experiment*) and kinetic studies reveal that this is a unimolecular decomposition.<sup>35</sup>

### 3 $\eta^1$ -COMPLEXES

#### 3.1 Alkyls, Aryls, Silyl, and Related $\sigma$ -Complexes

##### 3.1.1 Synthesis and Complexes

Metathesis reactions (see *Metathesis*) of Nb and Ta halide complexes with main group alkyls or milder alkylating reagents such as organozinc, -tin and -aluminum compounds (see **Zinc: Organometallic Chemistry**; **Tin: Organometallic Chemistry**, and **Aluminum: Organometallic Chemistry**), continue to be the most common approach to the formation of Nb– and Ta–C bonds.  $NaCp$  was used, for example, to give the  $\eta^1-C_5H_5$  ligands in  $Cp_2Nb(\eta^1-C_5H_5)_2$ <sup>36</sup> and  $Cp_2M(=NSiMe_3)(\eta^1-C_5H_5)$ .<sup>37</sup>

Migratory insertions (see *Migratory Insertion*) of alkenes or alkynes into M–H bonds are also a common method

to form the Nb and Ta alkyls. Such reactions with activated alkynes lead to the formation of  $\text{Cp}'_2\text{Nb}(\text{CNR})(\eta^1\text{-CR}'=\text{CHR}')$  and  $\text{Cp}'_2\text{Nb}(\text{CO})(\eta^1\text{-CR}'=\text{CHR}')$  ( $\text{R} = \text{Xyl}, \text{Cy}, \text{Bu}'$ ;  $\text{R}' = \text{CO}_2\text{Me}, \text{CO}_2\text{Bu}'$ ) from  $\text{Cp}'_2\text{Nb}(\text{H})(\text{CNR})$  and  $\text{Cp}'_2\text{Nb}(\text{H})(\text{CO})$ , respectively.<sup>38</sup>

A less common method to give  $\eta^1$ -alkyl or aryl complexes is the C–H bond activation reactions. Elimination of  $\text{HNMe}_2$  from  $\text{Ta}(\text{O}-2\text{-Ind-4,6-Bu}'_2\text{-C}_6\text{H}_3)(\text{NMe}_2)_4$  yields (14).<sup>39</sup> Activation of a C–H bond in a  $\text{Ta} \leftarrow \text{NMe}_2$  group led to the formation of the  $\text{Ta} \leftarrow \text{NMe-CH}_2$  moiety, as discussed in Section 9.1.<sup>40,41</sup>

Reactions of  $\text{TaMe}_5$  with triamines  $(\text{Me}_3\text{SiNHCH}_2\text{CH}_2)_2\text{-NH}$  and  $(\text{Me}_3\text{SiNH-}o\text{-C}_6\text{H}_4)_2\text{NH}$  yield  $[(\text{Me}_3\text{SiNCH}_2\text{-CH}_2)_2\text{N}]\text{TaMe}_2$  and  $[(\text{Me}_3\text{SiN-}o\text{-C}_6\text{H}_4)_2\text{N}]\text{TaMe}_2$ , respectively.  $(\text{C}_6\text{F}_5\text{NHCH}_2\text{CH}_2)_2\text{NH}$  reacts with  $\text{TaMe}_5$ , yielding first  $[(\text{C}_6\text{F}_5\text{NCH}_2\text{CH}_2)_2\text{NH}]\text{TaMe}_3$ , which then decomposes to  $[(\text{C}_6\text{F}_5\text{NCH}_2\text{CH}_2)_2\text{N}]\text{TaMe}_2$ .<sup>42</sup>

A review by Eisen summarizes chemistry of transition metal silyl chemistry between 1992 and mid-1996.<sup>43</sup> Earlier general references in this field include the reviews by Tilley and Schubert for the literature before 1992.<sup>44</sup> Nb silyl complexes  $\text{Cp}'_2\text{NbH}_2(\text{SiR}_3)$  ( $\text{SiR}_3 = \text{SiMe}_2\text{Ph}, \text{SiMePh}_2, \text{SiPhH}_2, \text{SiPh}_2\text{H}, \text{SiPh}_3$ ) have been prepared from the reactions of  $\text{Cp}'_2\text{NbH}_3$  with silanes  $\text{HSiR}_3$ .<sup>45</sup> In these silyl complexes, the silyl ligands occupy the central equatorial position. Reactions of  $\text{Cp}_2\text{NbH}_3$  or  $\text{Cp}_2\text{NbBH}_4$  with  $\text{HSiR}_3$  [ $\text{R}_3 =$ , for example,  $\text{Me}_2\text{Cl}, (\text{OEt})_3$ ] yield  $\text{Cp}_2\text{Nb}(\text{SiR}_3)\text{H}_2$ .<sup>46</sup> Disilyl hydrides  $\text{Cp}_2\text{NbH}(\text{SiMe}_2\text{X})_2$  are obtained by reactions of  $\text{Cp}_2\text{NbH}(\text{CH}_2=\text{CHPh})$  with  $\text{HSiMe}_2\text{X}$  ( $\text{X} = \text{Cl}, \text{Ph}$ ),<sup>47</sup> or reactions of  $\text{NbCp}_2(\text{SiMe}_2\text{Cl})_2\text{H}$  with  $\text{XSiMe}_3$  ( $\text{X} = \text{Br}, \text{I}$ ).<sup>48</sup> Similar reactions of  $\text{Ph}_3\text{EH}$  ( $\text{E} = \text{Ge}, \text{Sn}$ ) with  $\text{Cp}'_2\text{NbH}_3$  lead to the formation of  $\text{Cp}'_2\text{NbH}_2(\text{EPH}_3)$  ( $\text{E} = \text{Ge}, \text{Sn}$ ).<sup>49</sup>

$(\text{RCH}_2)_3\text{TaCl}_2$  ( $\text{R} = \text{Bu}', \text{Me}_3\text{Si}$ ) react with  $\text{LiSi}(\text{SiMe}_3)_3$ , affording Cp-free silyl alkylidene (see *Alkylidene*) complexes  $(\text{RCH}_2)_2\text{Ta}(\text{=CHR})\text{Si}(\text{SiMe}_3)_3$  ( $\text{R} = \text{Bu}', \text{Me}_3\text{Si}$ ).<sup>50,51</sup> Mechanistic studies (see *Mechanisms of Reaction of Organometallic Complexes*) of the formation of  $(\text{Me}_3\text{SiCH}_2)_2\text{Ta}(\text{=CHSiMe}_3)\text{Si}(\text{SiMe}_3)_3$  suggest that the intermediate  $(\text{Me}_3\text{SiCH}_2)_3\text{Ta}[\text{Si}(\text{SiMe}_3)_3]\text{Cl}$  undergoes  $\alpha$ -H abstraction (see  *$\alpha$ -Elimination*) with the elimination of  $\text{HSi}(\text{SiMe}_3)_3$  to give  $(\text{Me}_3\text{SiCH}_2)_2\text{Ta}(\text{=CHSiMe}_3)\text{Cl}$ .<sup>51,52</sup> Subsequent chloride replacement by the second equiv of  $\text{Si}(\text{SiMe}_3)_3^-$  gives the silyl alkylidene complex.

### 3.1.2 Reactions

Alkyl ligands in niobium and tantalum complexes are susceptible to attack by electrophiles (see *Electrophilic Reaction*). Hydrogenation (see *Hydrogenation*) of niobium or tantalum M–R bonds to provide the metal hydrides is an important reaction of synthetic utility. Insertion reactions of unsaturated reagents into Nb– or Ta–C bonds are common. The unsaturated reagents include alkenes, alkynes, CO, NO,  $\text{RN}=\text{C}=\text{NR}$ , CNR, and others.

Photolysis of  $\text{Ta}(\text{O}-2,6\text{-Ph}_2\text{-3,5-R}_2\text{-C}_6\text{H}_3)_2(\text{CH}_2\text{SiMe}_3)_3$  and  $^{\text{Ph}}[\text{P}_2\text{N}_2]\text{TaMe}_3$  yields alkylidenes  $\text{Ta}(\text{O}-2,6\text{-Ph}_2\text{-3,5-R}_2\text{-C}_6\text{H}_3)_2(\text{=CHSiMe}_3)(\text{CH}_2\text{SiMe}_3)$ <sup>53</sup> and  $^{\text{Ph}}[\text{P}_2\text{N}_2]\text{Ta}(\text{=CH}_2)(\text{Me})$ ,<sup>54</sup> respectively. In the presence of ethylene,  $^{\text{Ph}}[\text{P}_2\text{N}_2]\text{Ta}(\text{=CH}_2)(\text{Me})$  is slowly converted to  $^{\text{Ph}}[\text{P}_2\text{N}_2]\text{Ta}(\text{C}_2\text{H}_4)\text{Et}$  and  $^{\text{Ph}}[\text{P}_2\text{N}_2]\text{Ta}(\text{C}_2\text{H}_4)\text{Me}$ .<sup>54</sup>

Transition structures of  $\text{CH}_4$  elimination in  $\text{MMe}_5$  have been investigated in detail with *ab initio* (see *Ab Initio Calculations*) quantum mechanics calculations. The most favorable transition structure for the elimination is close to a trigonal-bipyramidal geometry. A dimeric mechanism through intermolecular hydrogen abstraction is found to be much lower in activation free energy than the unimolecular mechanism. The dimeric transition structure is mainly stabilized by an M–CH<sub>2</sub>–M bridge.<sup>55</sup>

Reactions of the silyl complex  $\text{Cp}_2\text{Ta}^{\text{III}}(\text{PMe}_3)(\text{SiBu}'_2\text{H})$  with  $\text{L} \rightarrow \text{BH}_3$  ( $\text{L} = \text{NEt}_3$ , N-methylmorpholine) give  $\text{Cp}_2\text{-Ta}(\mu\text{-H})_2\text{B}(\text{SiBu}'_2\text{H})\text{H}$  containing a B–Si bond.<sup>56</sup>

## 3.2 Hydride Complexes

Transition metal hydride (see *Hydrides*) derivatives are thought to be responsible for a plethora of organic transformations and catalytic cycles. The chemistry of Nb and Ta hydrides has developed rapidly in the past ten years. This part will focus on the synthetic and reactivity studies of these hydride complexes. A recent review surveyed the synthesis and reactivity of early metal hydride complexes.<sup>57</sup>

### 3.2.1 Cyclopentadienyl-free Hydride Complexes

Phosphines and alkoxides constitute common ancillary ligands in Cp-free hydride complexes. A  $\text{Ta}^{\text{IV}}$  penta-hydride  $[\text{TaH}_5(\text{dmpe})_2](\text{LiHBEt}_3)$  has been reported.<sup>58</sup> Hydrogenation of arenes is catalyzed by Nb and Ta hydrides with ancillary aryloxide ligation.<sup>59</sup> Reactions of alkynes and olefins with hydrides such as  $\text{Ta}(\text{O}-2,6\text{-Ph}_2\text{-C}_6\text{H}_3)_2(\text{H})_2\text{Cl}(\text{PMe}_3)_2$  were studied to explore the mechanistic pathways.<sup>60</sup> Reaction of  $[(\text{silox})_2\text{TaH}_2]_2$  with ethylene gives  $[(\text{silox})_2\text{HTaEt}]_2$  and  $[(\text{silox})_2\text{EtTa}](\mu\text{-CHCH}_2)(\mu\text{-H})_2[\text{Ta}(\text{silox})_2]$ .<sup>61</sup>

Hydrogenation of  $[\text{NPN}]\text{TaMe}_3$  [ $[\text{NPN}] = \text{PhP}(\text{CH}_2\text{-SiMe}_2\text{NPh})_2$ ] yields an interesting series of hydride-bridged dimers such as  $\{[\text{NPN}]\text{Ta}\}_2(\mu\text{-H})_4$ .<sup>62</sup> This  $\text{Ta}^{\text{IV}}$  complex, upon exposure to  $\text{N}_2$ , loses  $\text{H}_2$  to give a dinitrogen complex

$\{[NPN]Ta(\mu-H)_2(\mu-\eta^1:\eta^2-N_2)\}$  (**15**).<sup>63</sup> Reactions of silanes with the amido complex  $Ta(NMe_2)_5$  have been reported to give the dihydride  $\eta^2$ -imine complex (**16**).<sup>64</sup>

The niobaziridine-hydride  $Nb(H)[\eta^2-Bu^t(H)C=NAr]-[N(Np)Ar]_2$  ( $Ar = 3,5-Me_2-C_6H_3$ ), acting as a reactive synthon for its tautomer, the three-coordinate, trisamide  $Nb[N(Np)Ar]_3$ , reveals divergent reactivity for 2-electron reduction chemistry. It reacts with  $P_4$ , forming bridging diphosphide complex  $(\mu_2:\eta^2,\eta^2-P_2)\{Nb[N(Np)Ar]_3\}_2$ . In demonstrations of dual pathways of reactivity, nitriles and aldehydes insert into the  $Nb-H$  bond, leaving the niobaziridine ring intact.<sup>65</sup>

### 3.2.2 Cyclopentadienyl Hydrides

Important references of cyclopentadienyl hydrides include a review by Otero and coworkers, which covered the literature till mid-1998.<sup>66</sup>

$(\eta^5-C_5R_5)_2MH_3$  are useful stating hydrides of these two elements. Preparation of Nb silyl complexes from Nb hydrides is discussed in Section 3.1.1. In the studies of hydridosilyl complexes  $Cp(ArN=)Ta(PMe_3)(H)(SiCl_nR_{3-n})$  [ $Ar = 2,6-Pr^i_2-C_6H_3$ ,  $SiCl_nR_{3-n} = SiHMePh$ , (**17a**);  $SiClMe_2$ , (**17b**);  $SiCl_2Me$ , (**17c**);  $SiCl_3$ , (**17d**)], an unprecedented increase of the  $J_{Si-H}$  coupling constants between the hydride and silyl ligands from 14 Hz for (**17a**) to 50 Hz in (**17d**) was observed. This work shows that the increase in the magnitude of  $J_{Si-H}$  does not necessarily correspond to stronger bonding interaction between these two ligands.<sup>67</sup> The nature of possible  $H \cdots SiR_3$  interligand interactions in the complexes  $Cp_2MXH(SiR_3)$  ( $X = SiR_3, Cl, H, Me$ ) has been studied by *ab initio* calculations at the MP2 level. These theoretical studies indicate that the presence of a  $Si-Cl$  bond trans to hydride is

crucial to developing shortened  $H \cdots Si$  contacts and gives a concomitant lengthening of the  $Si-Cl$  bond.<sup>68</sup>

*cis*- $[Cp'_2Nb(HD)(PMe_2Ph)](CF_3CO_2)$  exhibits hindered rotation of the coordinated  $H-D$ . At 203 K, the *endo* H and *exo* H rotamers are observed, and they interconvert by rotation of the HD ligand reaching the coalescence at 233 K. This is the first observation of a freezing of  $H-D$  rotation on a transition metal complex.<sup>69</sup>

Insertion of  $ClPPH_2$  into  $M-H$  bonds in  $Cp_2MH_3$  and  $Cp'_2NbH$  gives phosphines  $[Cp_2MH_2(PHPh_2)]Cl$  ( $M = Nb$ ,<sup>70</sup>  $Ta$ <sup>71</sup>) and  $[Cp'_2NbH_2(PHPh_2)]Cl$ ,<sup>72</sup> which undergo deprotonation to yield  $Cp_2Nb^{III}H(PHPh_2)$ ,  $Cp_2Ta^VH_2(PPh_2)$ , and  $Cp'_2NbH(PHPh_2)$ , respectively. Similar reactions give  $Cp_2NbH_2AsR_2$ ,<sup>73</sup>  $Cp_2NbH_2SbPh_2$ ,<sup>74</sup>  $Cp_2NbH_2PbMe_3$ ,<sup>75</sup>  $Cp_2NbH_2BiPh_2$ ,<sup>76</sup> and  $Cp_2NbH_2GeR_3$ .<sup>77</sup> Protonation of  $Cp'_2NbH(L)$  ( $L = PHPh_2, CNXyl$ ) with  $CF_3COOH$  gives dihydrogen complexes  $[Cp'_2Nb(\eta^2-H_2)(L)](CF_3CO_2)$ .<sup>72,78</sup> Upon heating,  $[Cp'_2Nb(\eta^2-H_2)(PHPh_2)](CF_3CO_2)$  is converted to its transoiddihydride isomer. Reactions of  $(C_5H_4R)_2MH_3$  ( $R = H, SiMe_3$ ) with  $PH_2R'$  afford  $(C_5H_4R)_2-MH[(PR')_2]$  ( $R' = Ph, Cy$ ) with a  $MP_2$  ring, while the reaction of  $Cp_2TaH_3$  with white phosphorus gives  $Cp_2TaH[(PH)_2]$ .<sup>79</sup>

Reactions of silanes with cyclopentadienyl Ta imides are a new method to yield hydrides. Addition of the  $Si-H$  bond in  $PhSiH_3$  across the  $Ta=N$  double bond in  $Cp^*Ta[=N(C_6H_3Me)_2NSiMe_3]X$  ( $X = Cl, Me$ ) yields hydrides (**18**).<sup>80</sup> The reaction of  $Cp^*Ta(=N-Ar)[Si(SiMe_3)_3]H$  ( $Ar = 2,6-Pr^i_2-C_6H_3$ ) with  $PhSiH_3$  gives a mixture of hydrides  $[Cp^*(ArN=)TaH(\mu-H)]_2$ , (**19**), and (**20**).<sup>81</sup>

$(Bu^tC_5H_4)_2NbBH_4$  or  $(Bu^tC_5H_4)_2TaH_3$  reacts with Se to afford  $(Bu^tC_5H_4)_2Nb(\eta^2-SeSeH)$  and  $(Bu^tC_5H_4)_2Ta(\eta^2-Se_2)H$ .<sup>82</sup> Similar reactions of  $(Bu^tC_5H_4)_2NbH_3$  and  $Cp^*_2TaH_3$

with Te give  $(\text{Bu}'\text{C}_5\text{H}_4)_2\text{Nb}(\eta^2\text{-Te}_2)\text{H}^{83}$  and  $\text{Cp}^*_2\text{Ta}(\eta^2\text{-Te}_2)\text{H}^{84}$ . The telluroformaldehyde complex  $\text{Cp}^*_2\text{Ta}(\eta^2\text{-TeCH}_2)\text{H}$  has been prepared by the  $\text{PMe}_3$ -catalyzed addition of Te to the  $\text{Ta}=\text{CH}_2$  bond in  $\text{Cp}^*_2\text{Ta}(\text{CH}_2)\text{H}^{84}$ .

Insertion of alkynes  $\text{RC}\equiv\text{CR}'$  bearing electron-withdrawing substituents into  $\text{Nb-H}$  bonds in  $\text{Cp}'_2\text{NbH}(\text{L})$  ( $\text{L} = \text{CO}$ , isocyanide) and  $\text{Cp}'_2\text{NbH}_3$  were found to give alkenyl complexes  $\text{Cp}'_2\text{Nb}(\text{CR}=\text{CHR}')\text{L}$  and hydride olefin derivatives  $\text{Cp}'_2\text{Nb}(\text{CHR}=\text{CHR}')(\text{H})^{38}$ . The formation of the latter is believed to occur via initial stereospecific *trans*-insertion, followed by intramolecular rearrangement. Reactions of olefins  $\text{RCH}=\text{CH}_2$  with  $\text{Cp}'_2\text{NbH}_3$  yield  $\text{Cp}'_2\text{Nb}(\text{H})(\eta^2\text{-RCH}=\text{CH}_2)^{85}$ . Such olefin hydrides are also prepared from the alkylation of  $(\text{Cp}'_2\text{NbCl})_2$  with Grignard reagents  $\text{RMgX}$  ( $\text{R} = \text{Et}$ ,  $\text{CH}_2\text{CH}_2\text{Ph}$ ), followed by  $\beta$ -hydrogen elimination (see  *$\beta$ -Elimination*).<sup>86</sup>

Recent studies of the rates of H-exchange following intramolecular ethylene insertion into the  $\text{M-H}$  bond in *ansa*-metallocene (see *Metallocene Complexes*) complexes,  $[\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{H}_4)(\eta^5\text{-3-R-C}_5\text{H}_3)]\text{Nb}(\text{CH}_2\text{CH}_2)\text{H}$  ( $\text{R} = \text{Pr}^i$ ,  $\text{Bu}^t$ ), *rac*- and *meso*- $[\text{Me}_2\text{Si}(\eta^5\text{-3-Bu}^t\text{-C}_5\text{H}_3)_2]\text{-Nb}(\text{CH}_2\text{CH}_2)\text{H}$ , and  $[(1,2\text{-SiMe}_2)_2(\eta^5\text{-3,5-Pr}^i_2\text{-C}_5\text{H})(\eta^5\text{-4-Bu}^t\text{-C}_5\text{H}_2)]\text{Ta}(\text{CH}_2\text{CH}_2)\text{H}$ , show that the singly bridged *ansa*-niobocenes exchange up to three orders of magnitude faster than unbridged complexes. The doubly bridged *ansa*-tantalocene complex exchanges at a rate comparable to that previously reported for  $\text{Cp}^*_2\text{Ta}(\text{CH}_2\text{CH}_2)\text{H}$  and much slower than the singly bridged complex  $[\text{Me}_2\text{Si}(\eta^5\text{-C}_5\text{Me}_4)_2]\text{Ta}(\text{CH}_2\text{CH}_2)\text{H}$ . DFT calculations on model complexes indicate the presence of an agostic (see *Agostic Bonding*) ethyl intermediate in the computed exchange pathway.<sup>87</sup>

Reactions of  $\text{Cp}_2\text{NbH}_3$  with catecholborane or 9-borabicyclononane  $\text{HBR}_2$  yield disubstituted hydridoborates  $\text{Cp}_2\text{Nb}(\text{H}_2\text{BR}_2)$  via loss of  $\text{H}_2$ .<sup>88</sup> Ta boryl complexes *endo*- and *exo*- $\text{Cp}_2\text{Ta}(\text{H})_2(\text{BO}_2\text{C}_6\text{H}_4)$  are prepared from the reaction of chlorocatecholborane with  $(\text{Cp}_2\text{TaH}_2\text{Li})_x$ .<sup>89</sup> *ansa*-Niobiocene tetrahydride complexes  $[(\text{C}_5\text{H}_4)\text{X}(\text{C}_5\text{H}_4)]\text{Nb}(\eta^2\text{-BH}_4)$  ( $\text{X} = \textit{ansa}-bridging unit) are prepared as well,<sup>90</sup> and the barrier to bridge-terminal hydrogen exchange is considerably reduced when the bridging unit imposes significant structural changes in the metallocene (see *Metallocene Complexes*). Theoretical studies of catecholborane adducts of hydride complexes  $\text{Cp}_2\text{M}(\text{H})$  that are obtained from  $\text{Cp}_2\text{M}(\text{H})(\eta^2\text{-CH}_2=\text{CH}_2)$  show that there are structural isomers of the *O*- and *N*-substituted borane adducts including boryl, hydridoborate, and  $\sigma$ -complex structures. These structures are related to how the electron-deficient (see *Electron Deficient Compound*) B atom is electronically saturated.<sup>91</sup>$

Dianionic borollide complexes  $\text{Cp}^*(\text{C}_4\text{H}_4\text{B-R})\text{TaMe}_2$  have been prepared and found to undergo hydrogenolysis in the presence of  $\text{PMe}_3$  to give  $\text{Cp}^*(\text{C}_4\text{H}_4\text{B-R})\text{Ta}(\text{H})_2(\text{PMe}_3)$  (**21a**).<sup>92,93</sup>  $[\text{C}_4\text{H}_4\text{BNPr}^i_2](\text{C}_5\text{H}_5\text{BPh})\text{Ta}(\text{H})_2\text{PEt}_3$  (**21b**) is similarly prepared.<sup>12</sup>

Treatment of the imide hydride  $\text{Cp}^*_2\text{Ta}(\text{=NBu}')\text{H}$  with  $[\text{Ph}_3\text{C}][\text{B}(\text{C}_6\text{F}_5)_4]$  yields the cationic imide  $[\text{Cp}^*_2\text{Ta}(\text{=NBu}')(\text{THF})][\text{B}(\text{C}_6\text{F}_5)_4]$  (**22**). (**22**) reacts cleanly with  $\text{H}_2$  to yield  $[\text{Cp}^*_2\text{Ta}(\text{NHBu}')\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$ , and undergoes C-H bond activation reactions with propyne or phenylacetylene to afford  $[\text{Cp}^*_2\text{Ta}(\text{NHBu}')(\text{C}\equiv\text{CR})][\text{B}(\text{C}_6\text{F}_5)_4]$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ ). The heterolytic cleavage reactions of (**22**) may be the result of the presence of both electrophilic and nucleophilic sites of reactivity in the same molecule. Intramolecular activation of a C-H bond of a  $\text{Cp}^*$  lig-

and yields  $[\text{Cp}^*\text{Ta}(\eta^5\text{-C}_5\text{Me}_4\text{CH}_2\text{NBu}')\text{H}][\text{B}(\text{C}_6\text{F}_5)_4]$  with the methylene group attached to the N rather than the Ta atom. Dealkylation of the imido group is observed in an unusual reaction of (**22**) with  $\text{CO}_2$  giving isobutylene and the isocyanate complex  $[\text{Cp}^*_2\text{Ta}(\text{OH})(\text{NCO})][\text{B}(\text{C}_6\text{F}_5)_4]$ .<sup>94</sup>

Reactions of  $(\text{C}_5\text{H}_4\text{Bu}')_2\text{Ta}(\text{=S})\text{H}$  with  $\text{PhNCS}$  and  $\text{HCl}$  exhibit a surprisingly low hydride reactivity. The  $\text{Ta}=\text{S}$  bond is involved either in a  $[2+2]$  cycloaddition giving  $(\text{C}_5\text{H}_4\text{Bu}')_2\text{Ta}(\text{H})[\text{S-C(=S)-NPh}]$  or in a protonation yielding  $(\text{C}_5\text{H}_4\text{Bu}')_2\text{Ta}(\text{H})\text{Cl}_2$ .<sup>95</sup>

Reduction of the allene complex  $\text{Cp}^*_2\text{Ta}_2(\mu\text{-X})\text{X}_3(\mu\text{-}\eta^1, \eta^3\text{-C}_3\text{H}_4)$  ( $\text{X} = \text{Cl}$ ,  $\text{Br}$ ) with  $\text{Na/Hg}$  gives  $\text{Cp}^*_2\text{Ta}_2(\mu\text{-H})_2\text{X}_2(\mu\text{-HCCCCH})$  (**23**). The reactions proceed via a double 1,3-C-H activation, with  $\text{C}_3\text{H}_2$  and two  $\mu$ -hydride ligands instead of an allenyl hydride.<sup>96</sup>

Selective conversion of an ethylene to an ethylidene ligand in reactions of a  $\text{Cp}_2\text{Ta}(\text{C}_2\text{H}_4)\text{H}$  with iodofluorocarbons has been reported. Reactions of  $\text{Cp}_2\text{Ta}(\text{C}_2\text{H}_4)\text{H}$  with perfluorobutyl iodide or perfluorobenzyl iodide, and perfluoro-*iso*-Pr iodide or pentafluorophenyl iodide are found to yield the ethylene complex  $\text{Cp}_2\text{Ta}(\text{C}_2\text{H}_4)\text{I}$  and the ethylidene complex  $\text{Cp}_2\text{Ta}(\text{CHMe})\text{I}$ , respectively. No interconversion of these two isomers is observed under these reaction conditions, indicating that each is formed under conditions of kinetic control.<sup>97</sup>

Thermodynamic studies of hydride transfer from  $\text{Cp}_2\text{M}(\text{H})\text{L}$ ,  $\text{Cp}^*_2\text{M}(\text{H})\text{L}$ ,  $\text{Cp}'_2\text{M}(\text{H})\text{L}$  [ $\text{L} = \text{CO}$ ,  $\text{PEt}_3$ ,  $(\text{H})_2$ ,  $\text{PhC}\equiv\text{CPh}$ ,  $\text{CH}_2=\text{O}$ ,  $=\text{O}$ ], and  $\text{Cp}'_2\text{Nb}(\text{Cl})(\text{L}')$  ( $\text{L}' =$

O=C=CETPh, O=C=CET<sub>2</sub>) to Ar<sub>3</sub>C<sup>+</sup> indicate that the free energies of hydride transfer are heavily influenced by coligands, but less so by 4d versus 5d effects in isostructural Nb or Ta complexes.<sup>98</sup>

### 3.2.3 Heterobimetallic Complexes

Hydride complexes discussed here include both  $\mu$ -hydride heterobimetallic complexes, and bimetallic complexes with Nb–H or Ta–H ligands.

Reduction of Cp<sub>2</sub>Nb(SiMe<sub>2</sub>Cl)H<sub>2</sub> with LiAlH<sub>4</sub> gives [Cp<sub>2</sub>Nb( $\mu$ -H)<sub>2</sub>AlH( $\mu$ -H)]<sub>2</sub>.<sup>48</sup> Reactions of Cp<sub>2</sub>TaH<sub>3</sub> with M(CO)<sub>6</sub> also give  $\mu$ -hydride heterobimetallic complexes Cp<sub>2</sub>TaH<sub>2</sub>( $\mu$ -H)M(CO)<sub>5</sub> (M = Cr, Mo, W).<sup>99</sup> [(Cp'<sub>2</sub>NbH<sub>3</sub>)<sub>2</sub>M]-(PF<sub>6</sub>) (M = Cu, Ag, Au) are prepared via the reactions of Cp'<sub>2</sub>NbH<sub>3</sub> with [Cu(MeCN)<sub>4</sub>]PF<sub>6</sub>, AgBF<sub>4</sub>, or 'Au(THT)PF<sub>6</sub>'.<sup>100</sup> Tantalum analogues [(C<sub>5</sub>H<sub>4</sub>Bu')<sub>2</sub>TaH<sub>3</sub>-MPPH<sub>3</sub>](PF<sub>6</sub>) (M = Cu, Au) have also been prepared from the reactions of (C<sub>5</sub>H<sub>4</sub>Bu')<sub>2</sub>TaH<sub>3</sub> with (MPPH<sub>3</sub>)(PF<sub>6</sub>).<sup>101</sup> NMR studies are consistent with two bridging hydride ligands between the disparate metals centers. Cp'<sub>2</sub>NbH(CO) reacts with [Cu(MeCN)<sub>4</sub>]BF<sub>4</sub>, CuPPh<sub>3</sub>Cl/TIPF<sub>6</sub>, AgBF<sub>4</sub>, AgPPh<sub>3</sub>Cl/TIPF<sub>6</sub>, and Au(THT)Cl/TIPF<sub>6</sub>, giving [(Cp'<sub>2</sub>Nb(CO))<sub>2</sub>( $\mu$ -H)<sub>2</sub>M]<sup>+</sup> (M = Cu, Ag, Au), whereas the reaction with [Au(PPh<sub>3</sub>)]<sup>+</sup> leads to [(Cp'<sub>2</sub>Nb(CO))( $\mu$ -H)Au]PF<sub>6</sub>.<sup>102</sup>

Electrophilic addition of the Lewis acid B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> to Cp<sub>2</sub>TaH<sub>3</sub> yields Cp<sub>2</sub>TaH<sub>2</sub>[ $\eta^1$ -HB(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>].<sup>103</sup> Protonation of Cp<sub>2</sub>TaH(CO) by HBF<sub>4</sub>·Et<sub>2</sub>O gives a dihydrogen complex Cp<sub>2</sub>TaH<sub>2</sub>(CO)<sup>+</sup>BF<sub>4</sub><sup>-</sup>. This complex exists as two isomers. The minor isomer is a *trans*-dihydride, and the major isomer is [Cp<sub>2</sub>Ta( $\eta^2$ -H<sub>2</sub>)(CO)]BF<sub>4</sub>, the first thermally stable group 5 dihydrogen complex. Protonation of the silyl hydride Cp<sub>2</sub>TaH<sub>2</sub>(SiMe<sub>2</sub>Ph) gives a dinuclear complex [(Cp<sub>2</sub>TaH<sub>2</sub>)<sub>2</sub>( $\mu$ -H)]{B[3,5-(CF<sub>3</sub>)<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>]<sub>4</sub>}.<sup>104</sup> Organocyclichydroborate complexes of niobocenes Cp<sub>2</sub>Nb<sup>III</sup>( $\mu$ -H)<sub>2</sub>BR<sub>2</sub>, where R<sub>2</sub> is, for example, *cyclic*-(CH<sub>2</sub>)<sub>n</sub>- (n = 4, 5), are prepared from the reductions of Cp<sub>2</sub>Nb<sup>IV</sup>Cl<sub>2</sub> with the hydroborate salts.<sup>105</sup> Reactions of Cp<sub>2</sub>Nb<sup>III</sup>( $\mu$ -H)<sub>2</sub>B(C<sub>5</sub>H<sub>10</sub>) with B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> are solvent-dependant, yielding cationic [Cp<sub>2</sub>Nb( $\mu$ -H)( $\eta^5$ ,  $\eta^1$ -C<sub>5</sub>H<sub>4</sub>)Nb( $\eta^5$ ,  $\eta^1$ -C<sub>5</sub>H<sub>4</sub>)<sub>2</sub>Nb{( $\mu$ -H)( $\eta^5$ -C<sub>5</sub>H<sub>4</sub>B(C<sub>6</sub>F<sub>5</sub>)<sub>2</sub>)}]<sup>+</sup> in toluene and neutral CpNb(C<sub>6</sub>F<sub>5</sub>){( $\mu$ -H)[ $\eta^5$ -C<sub>5</sub>H<sub>4</sub>B(C<sub>6</sub>F<sub>5</sub>)<sub>2</sub>]} in diethyl ether.<sup>106</sup>

## 4 ALKYLIDENES AND ALKYLIDYNES

### 4.1 Synthesis and Complexes

A recent paper by Schrock reviewed chemistry of complexes with high-oxidation-state metal-carbon multiple bonds.<sup>107</sup>

The most common approach to alkylidene (*see Alkylidene*) and alkylidyne (*see Alkylidyne*) complexes involves  $\alpha$ -hydrogen abstraction from bis(alkyl) and alkyl-alkylidene complexes to give alkylidenes and alkylidynes, respectively. Short-lived TaNp<sub>5</sub> is directly observed as an intermediate in the formation of the first alkylidene Np<sub>3</sub>Ta=CHBu' from the alkylation of TaNp<sub>4</sub>Cl.<sup>108</sup> Ta(CH<sub>2</sub>SiMe<sub>3</sub>)<sub>5</sub>, which is less bulky and thus more stable than TaNp<sub>5</sub>, is isolated. It converts to alkylidene (Me<sub>3</sub>SiCH<sub>2</sub>)<sub>3</sub>Ta=CHSiMe<sub>3</sub> and then to bridging alkylidyne (Me<sub>3</sub>SiCH<sub>2</sub>)<sub>4</sub>Ta<sub>2</sub>( $\mu$ -CSiMe<sub>3</sub>)<sub>2</sub>. The first and second conversions follow first-order [ $\Delta H_1 = 21.6(1.4)$  kcal mol<sup>-1</sup> and  $\Delta S_1 = -5(5)$  e.u.] and second-order kinetics [ $\Delta H_2 = 6.2(0.3)$  kcal mol<sup>-1</sup> and  $\Delta S_2 = -61.6(0.8)$  e.u.], respectively.<sup>108</sup> Dialkylation of [N<sub>3</sub>N]TaCl<sub>2</sub> and [N<sub>3</sub>N\*]TaCl<sub>2</sub> with RCH<sub>2</sub>Li or RCH<sub>2</sub>MgCl (R = for example, Et, Pr<sup>n</sup>, and Bu<sup>i</sup>) yields [N<sub>3</sub>N]Ta=CHR and [N<sub>3</sub>N\*]Ta=CHR, respectively. Alkylation of [N<sub>3</sub>N]TaCl<sub>2</sub> and [N<sub>3</sub>N\*]TaCl<sub>2</sub> with EtMgCl gives ethylene complexes [N<sub>3</sub>N]Ta(C<sub>2</sub>H<sub>4</sub>) and [N<sub>3</sub>N\*]Ta(C<sub>2</sub>H<sub>4</sub>).<sup>109–111</sup> Reactions of Cp\*Ta(N=PR<sub>3</sub>)Cl<sub>3</sub> (R = Bu<sup>t</sup>, Pr<sup>i</sup>) with PhCH<sub>2</sub>MgCl similarly afford Cp\*Ta(N=PR<sub>3</sub>)(=CHPh)(CH<sub>2</sub>Ph).<sup>112</sup>

Reactions of phenols (ArOH) with (RCH<sub>2</sub>)<sub>4</sub>Ta<sub>2</sub>( $\mu$ -CR)<sub>2</sub> (R = SiMe<sub>3</sub>) lead to the substitution of an alkyl ligand to give (ArO)(RCH<sub>2</sub>)<sub>3</sub>Ta<sub>2</sub>( $\mu$ -CR)<sub>2</sub>. Such a reaction follows second-order kinetics with a strong kinetic isotope effect ( $k_H/k_D$ ), and the rates strongly depend on the nature of the phenol substituents.<sup>113</sup>

The alkylidenes or alkylidynes can also be prepared by the intermolecular deprotonation reactions. Reaction of [PhC(NSiMe<sub>3</sub>)<sub>2</sub>]TaCl(CH<sub>2</sub>Ph)<sub>3</sub> with LiN(SiMe<sub>3</sub>)<sub>2</sub> affords [PhC(NSiMe<sub>3</sub>)<sub>2</sub>]Ta(=CHPh)(CH<sub>2</sub>Ph)<sub>2</sub>.<sup>24</sup> An unusual alkylidene complex CpTa(NEt<sub>2</sub>)<sub>2</sub>(=C<sub>5</sub>H<sub>4</sub>) was prepared from the reaction of CpTa(NEt<sub>2</sub>)<sub>2</sub>Cl<sub>2</sub> with MeLi.<sup>114</sup>

Phosphorus ylides (*see Ylide*) are useful reagents to introduce alkylidene groups to Nb or Ta complexes. Ph<sub>3</sub>P=CH<sub>2</sub> reacts with Cp<sub>2</sub>M(=NBu')Cl<sub>2</sub> (M = Ta, Nb) yielding Cp<sub>2</sub>M(=NBu')(CHPPh<sub>3</sub>)Cl. Treatment of the Nb complex with an excess of Ph<sub>3</sub>P=CH<sub>2</sub> leads to Cp<sub>2</sub>Nb(=NBu')(CHPPh<sub>3</sub>)<sub>2</sub>.<sup>115</sup>

Alkene metathesis (*see Alkene Metathesis*) reactions have also been used to give isolable alkylidenes. Reactions of Ta(=CHBu')[NCN](OBu')X (X = Cl, **24a**; OBu', **24b**) with Me<sub>3</sub>SiCH=CH<sub>2</sub> afford Ta(=CHSiMe<sub>3</sub>)[NCN](OBu')X stabilized by *ortho*-chelating arylamine ligands.<sup>116</sup>

Several other approaches have led to the formation of alkylidene and carbene complexes. Substitution of pyridine ligands in  $\text{MCl}_4(\text{py})_2$  by nucleophilic cyclocarbene 1,3-dimethylimidaxolin-2-ylidene (**25**) gives  $\text{MCl}_4\text{L}_2$ .<sup>117</sup>

Rearrangement of the ethylene ligand in  $[\text{N}_3\text{N}]\text{Ta}(\text{H}_2\text{C}=\text{CH}_2)$  affords  $[\text{N}_3\text{N}]\text{Ta}=\text{CHMe}$ , and this reaction is catalyzed by  $\text{PhPH}_2$ .<sup>109,110</sup> Reaction of  $\text{Cp}^*\text{TaCl}_4$  with phosphavinyl Grignard reagent  $(Z)\text{-MgCl}\{\text{C}(\text{Bu}')=\text{PCy}\}$  gives a novel bis(phosphinoalkylidene) complex  $\{\text{Cp}^*\text{TaCl}_2\text{-}[\text{C}(\text{Bu}')\text{-P}(\text{Cy})\text{-}]\}_2$  (**26**).<sup>118</sup>

Bimetallic complexes containing bridging alkylidene and alkylidyne ligands have been prepared using alkylating reagents. Ta-Zn neophylidyne  $\{[\text{TaCl}_2(\mu\text{-CCMe}_2\text{Ph})(\mu\text{-Cl})(\text{THF})_2][\text{Zn}(\mu\text{-Cl})]\}_2$  is a good starting material for the synthesis of alkylidynes such as the Ta-Zn neophylidynes (**27**) and (**28a**), where the alkylidyne functionality and the aryl ipso-carbon bridge between the Zn and Ta centers. The reaction of  $\text{TaCl}_2[\text{NCN}](=\text{CHBu}')$  with  $\text{NpZnCl}$  affords (**28b**), an analog of (**28a**).<sup>41</sup> (**28a-b**) react with TMEDA leading to C-H activation of the methyl group in  $\text{-NMe}_2$ , a subject discussed in Section 9.1.<sup>119</sup>

(R =  $\text{CMe}_2\text{Ph}$ , **28a**;  $\text{Bu}'$ , **28b**)

## 4.2 Reactions

The reactions of alkylidenes (see *Alkylidene*) and alkylidynes (see *Alkylidyne*) of niobium and tantalum are typically characterized by nucleophilic alkylidene and alkylidyne ligands.  $\text{Cp}^*\text{Ta}(\text{CH}_2\text{SiMe}_3)_2(=\text{CHSiMe}_3)$  reacts with  $\text{PhOH}$  to give alkyl phenoxo  $\text{Cp}^*\text{Ta}(\text{CH}_2\text{SiMe}_3)_3(\text{OPh})$ , and is hydrolyzed in the presence of a trace amount of  $\text{H}_2\text{O}$  to give the oxo dialkyl derivative  $[\text{Cp}^*\text{Ta}(\text{CH}_2\text{SiMe}_3)_2\text{O}]_n$ .<sup>120</sup>

Nb and Ta alkylidenes readily undergo metathesis reactions (see *Alkene Metathesis*) with carbonyl functionalities or imines to form alkene and  $\text{M}=\text{O}$  or  $\text{M}=\text{NR}$  bonds. Reactions of  $(\text{Me}_3\text{SiCH}_2)(\text{ArN}=\text{Ta})(\mu\text{-CHSiMe}_3)(\mu\text{-}\eta^1:\eta^3\text{-Pr}^i_2\text{-tacn})\text{Li}$  ( $\text{Pr}^i_2\text{-tacn}^-$  = anionic triazacyclononane, **29**) with  $\text{Ph}_2\text{C}=\text{O}$  give  $[(\text{Me}_3\text{SiCH}_2)(\text{RN}=\text{Ta})(\mu\text{-O})(\mu\text{-}\eta^1:\eta^3\text{-Pr}^i_2\text{-tacn})\text{Li}]_2$ .<sup>121</sup>

In some cases, hydrogenation of the alkylidenes and alkylidynes reduces the metal-carbon multiple bonds to single bonds. The alkylidene ligand in (**29**) is converted to an alkyl group when exposed to  $\text{H}_2$ , leading to the formation of an interesting tantalum-lithium bridging hydride complex.<sup>122</sup>

The reactions of alkylidene with alkenes typically afford metallacyclic complexes (see *Metallacycle*), a subject discussed in Section 6.1.  $\text{Ta}(\text{CHR})[\text{CNN}](\text{OBu}')_2$  (R =  $\text{Bu}'$ , **30a**;  $\text{CMe}_2\text{Ph}$ , **30b**) reacts with ethene to afford the tantalacyclobutane complex  $\text{Ta}[(\text{CH}_2)_3\text{-1,3}][\text{CNN}](\text{OBu}')_2$  (**31a**) at room temperature. Under heating, (**30b**) reacted with ethene to give  $\text{Ta}[\text{CNN}](\text{OBu}')_2(\text{H}_2\text{C}=\text{CH}_2)$ .<sup>123</sup>

Reactions of  $[\text{ToIC}(\text{NSiMe}_3)_2]_2\text{Ta}(\text{CH}_2=\text{CH}_2)\text{Me}$  with pyridine N-oxides proceed via regioselective methylene transfer to afford 2-methylpyridines and  $[\text{ToIC}(\text{NSiMe}_3)_2]_2\text{Ta}(\text{O})\text{CH}_3$ , while the reaction with the nitron  $\text{PhCH}=\text{N}(\rightarrow\text{O})\text{Bu}'$  leads to  $[\text{ToIC}(\text{NSiMe}_3)_2]_2\text{Ta}(\text{O})(\text{NMeBu}')$  and  $\text{PhCH}=\text{CH}_2$ .<sup>124</sup>

The mechanism of  $\text{H}_2$  addition to  $\text{Cp}^*_2\text{Ta}(\text{CH}_2=\text{CH}_2)\text{H}$  has been studied using parahydrogen-induced polarization (PHIP),  $^{13}\text{C}$  labeling, and comparison to the related complex  $\text{Cp}^*_2\text{Ta}(\text{CH}_2=\text{CH}_2)\text{Me}$ . The reaction of *para*-enriched  $\text{H}_2$  with labeled  $\text{Cp}^*_2\text{Ta}(\text{CH}_2=\text{CH}_2)\text{H}$  leads to polarized resonances for both  $\text{Cp}^*_2\text{TaH}_3$  and  $\text{Cp}^*_2\text{Ta}(\text{CH}_3)_2\text{H}_2$ , where the polarized resonances correspond to the two hydride ligands. The results thus support a pathway of  $\text{H}_2$  addition to a Ta(III) intermediate  $\text{Cp}^*_2\text{TaCH}_3$ , rather than addition directly across the  $\text{Ta}=\text{C}$  bond.<sup>125</sup>

Surface chemistry of the alkyl/alkylidene complexes has been studied by  $^{13}\text{C}$  CPMAS NMR spectroscopy.  $\text{Cp}_2\text{Ta}(\text{CH}_2=\text{CH}_2)(\text{CH}_3)$  is converted predominantly to a stable cation-like  $\text{Cp}_2\text{Ta}(\text{CH}_3)_2^+$  species on partially dehydroxylated  $\text{SiO}_2$  (PDS) presumably via electrophilic addition of a proton from the PDS surface. The formation of cation-like  $\text{Cp}_2\text{Ta}(\text{CH}_3)_2^+$  and  $\text{CpTa}(\text{CH}_3)_3^+$  is observed when  $\text{Cp}_2\text{Ta}(\text{CH}_3)_3$  and  $\text{CpTa}(\text{CH}_3)_4$  are chemisorbed on PDS and dehydroxylated  $\text{SiO}_2$  (DS),

and on dehydroxylated  $\gamma$ -alumina, respectively. In comparison,  $(\text{Bu}^t\text{CH}_2)_3\text{Ta}=\text{CHBu}^t$  forms predominantly a  $\text{Ta}(\text{CH}_2\text{CHBu}^t)(\text{CH}_2\text{CH}_2\text{Bu}^t)_2\text{O-Si}$ ,  $\mu$ -oxo-alkylidene species on PDS.<sup>126</sup>

The conversion of  $\text{NH}_3$  and pentamer  $[\text{Nb}_2\text{Ta}_3\text{N}]_5$ , which had been prepared from  $\text{Nb}_3\text{Ta}=\text{CHBu}^t$  and  $\text{NH}_3$ , to cubic  $\text{Ta}_2\text{N}_{0.8}$  is found to proceed via precipitate  $1/n[\text{Ta}_{1.41}\text{H}_{3.90}\text{N}_{1.90}]_n$  at  $80^\circ\text{C}$  and amorphous  $\text{Ta}_2\text{N}$  at  $400^\circ\text{C}$ . The latter was then converted to cubic  $\text{Ta}_2\text{N}_{0.8}$  at  $820^\circ\text{C}$ .<sup>127</sup>

## 5 $\eta^2$ -COMPLEXES

### 5.1 Alkene Complexes

Alkene complexes of niobium and tantalum are of great interest in large part because they are implicated in polymerization, metathesis, and dimerization reactions of alkenes (see *Oligomerization & Polymerization by Homogeneous Catalysis* and *Metathesis Polymerization Processes by Homogeneous Catalysis*). Nb and Ta alkene complexes are usually prepared from: (i) direct alkene coordination to metal centers. Substitution of the 4-picoline ligand in  $(\text{silox})_3\text{Nb}(\eta\text{-C}_4\text{H}_7\text{N})$  (4-picoline) by COT, followed by dehydrogenation, gives the cyclooctatrieneyne complex  $\{(\text{silox})_3\text{Nb}\}_2(\eta\text{-1,2};\eta\text{-5,6-C}_8\text{H}_6)$ . Treatment of this complex with  $\text{H}_2$  leads to a rearrangement to the alkylidene-yne  $\{(\text{silox})_3\text{Nb}\}_2(\eta^1;\eta^2\text{-4,5-C}_8\text{H}_6)$ .<sup>128</sup> (ii)  $\beta$ -Hydrogen abstraction (see  *$\alpha$ -Elimination*) in dialkyl complexes. One such example is the reaction of  $[\text{N}_3\text{N}]\text{TaCl}_2$  with 2 equiv of  $\text{EtMgCl}$  to give  $[\text{N}_3\text{N}]\text{Ta}(\text{H}_2\text{C}=\text{CH}_2)$ .<sup>109,110</sup> The presence of a catalytic amount of  $\text{PhPH}_2$  leads to the conversion of  $[\text{N}_3\text{N}]\text{Ta}(\text{H}_2\text{C}=\text{CH}_2)$  to the ethylidene complex  $[\text{N}_3\text{N}]\text{Ta}=\text{CHMe}$ .<sup>110</sup> Alkylation of  $\text{Cp}^*\text{Ta}(\text{NPR}_3)\text{Cl}_3$  ( $\text{R} = \text{Bu}^t, \text{Pr}^i$ ) with 2 equiv of  $\text{EtMgCl}$  results in formation of  $\text{Cp}^*\text{Ta}(\text{NPR}_3)(\eta^2\text{-C}_2\text{H}_4)\text{Cl}$ . Substitution of the remaining chloride by  $\text{EtMgCl}$  affords  $\text{Cp}^*\text{Ta}(\text{NPR}_3)(\eta^2\text{-C}_2\text{H}_4)(\text{Et})$ .<sup>112</sup> (iii)  $\beta$ -Hydride elimination in unsaturated  $d^3$  complexes. The olefin-hydride complexes *endo*- $\text{Cp}'_2\text{Nb}(\text{H})(\eta^2\text{-RHC}=\text{CH}_2)$  ( $\text{R} = \text{H}, \text{Ph}$ ) are prepared by alkylation of  $(\text{Cp}'_2\text{NbCl})_2$  with  $\text{RCH}_2\text{CH}_2\text{MgX}$  followed by a stereoselective  $\beta$ -H elimination from  $\text{Cp}'_2\text{Nb}(\text{CH}_2\text{CH}_2\text{R})$ . In comparison, reactions of  $\text{Cp}'_2\text{NbH}_3$  with styrene or other olefins give a mixture of *endo*- and *exo*-isomers.<sup>85,86</sup> Similarly,  $\text{Cp}'_2\text{NbR}'[\eta^2\text{-(C,Z)-ZCCRPh}]$  ( $\text{Z} = \text{NPh}, \text{R} = \text{Ph}, \text{Me}, \text{Et}, \text{H}; \text{Z} = \text{O}, \text{R} = \text{Ph}; \text{R}' = \text{H}, \text{Me}, \text{Et}$ ), prepared from  $\text{Cp}'_2\text{NbCl}[\eta^2\text{-(C,Z)-ZCCRPh}]$  and  $\text{R}'\text{MgI}$  or  $\text{R}'_2\text{Mg}$ , readily undergo the loss of the ketene ligand and subsequent  $\beta$ -hydride elimination to form  $\text{Cp}'_2\text{NbH}(\eta^2\text{-CH}_2=\text{CH}_2)$ .<sup>129</sup> (iv) Reductive addition of alkynes to the hydride complexes.  $\text{Cp}'_2\text{Nb}(\text{H})[\eta^2\text{-RO}_2\text{C(H)=C(H)CO}_2\text{R}]$  ( $\text{R} = \text{Me}, \text{Bu}^t$ ) and  $\text{Cp}'_2\text{Nb}(\text{H})(\eta^2\text{-MeO}_2\text{CH}=\text{CH}_2)$  are prepared from  $\text{Cp}'_2\text{NbH}_3$  and active alkynes  $\text{RO}_2\text{CC}\equiv\text{CCO}_2\text{R}$  or  $\text{MeO}_2\text{CC}\equiv\text{CH}$ .<sup>38</sup>

Substitution of two chloride ligands in  $[\eta^5\text{-C}_4\text{H}_4\text{BN}(\text{CHMe}_2)_2]\text{TaCl}_3$  by methylcyclopentadienyl  $\text{MeC}_5\text{H}_4^-$  affords  $\eta^2$  borollide  $(\text{MeC}_5\text{H}_4)_2[\eta^2\text{-C}_4\text{H}_4\text{BN}(\text{CHMe}_2)_2]\text{-TaCl}$ .<sup>12</sup>

### 5.2 Alkyne and Benzyne Complexes

Nb and Ta alkyne complexes are of interest in part because they have found use in organic synthesis and cyclooligomerization (see *Cyclodimerization & -trimerization Reactions*) of alkynes.

#### 5.2.1 Alkyne Complexes without Cyclopentadiene Ligands

Reactions of low-valent Nb and Ta complexes with alkynes are one of the simplest methods to prepare the alkyne complexes. Substitution of a CO and  $\text{PR}_3$  ligand in  $\text{INb}(\text{CO})_3(\text{PR}_3)_3$  by diynes gives  $\text{INb}(\text{CO})_2(\text{PR}_3)_2(\text{diyne})$  ( $\text{PR}_3 = \text{PEt}_3$ ; diyne = 2,4-hexadiyne, 1,5-hexadiyne;  $\text{PR}_3 = \text{PMe}_2\text{Ph}$ , diyne = 2,6-octadiyne). When  $\text{Ph}_2\text{PCCPh}_2$  is used, its reaction with  $\text{INb}(\text{CO})_3(\text{PMe}_2\text{Ph})_3$  affords  $\text{INb}(\text{CO})_2(\text{PMe}_2\text{Ph})_2(\text{Ph}_2\text{PC}\equiv\text{CPh}_2)$ .<sup>130</sup>  $[\text{Nb}(\eta^2\text{-F}_3\text{CC}\equiv\text{CCF}_3)(\text{py})\text{-Br}_4]^-$  is obtained from the reaction of  $[\text{Nb}(\text{CO})_6]^-$ ,  $\text{F}_3\text{CC}\equiv\text{CCF}_3$ , and  $[\text{Hpy}]\text{Br}$ .<sup>131</sup> Treatment of alkynes with low-valent Ta species derived from the reduction of  $\text{TaCl}_5$  with Zn yields  $\text{TaCl}_3(\text{R}^1\text{C}\equiv\text{CR}^2)(\text{dme})$  ( $\text{R}^1 = \text{Et}, n\text{-C}_5\text{H}_{11}, \text{Ph}$ ;  $\text{R}^2 = \text{Et}, n\text{-C}_5\text{H}_{11}, \text{Me}, \text{Ph}$ ).<sup>132</sup>  $\text{Tp}^*\text{NbCl}_2(\text{alkyne})$  (alkyne =  $\text{PhC}\equiv\text{CMe}$ ,  $\text{PhC}\equiv\text{CEt}$ ,  $\text{PhC}\equiv\text{CPr}^i$ ,  $\text{MeC}\equiv\text{CMe}$ ,  $\text{PhC}\equiv\text{CPh}$ ) have been prepared from the high-yield, one-pot reaction of  $\text{NbCl}_3(\text{DME})$  first with an alkyne and then with  $\text{KTp}^*$ .<sup>133,134</sup> Alkyne adducts  $\text{Tp}^*\text{Nb}(\text{CO})(\text{PhC}\equiv\text{CMe})(\text{L})$  ( $\text{L} = \text{RCN}, \text{PMe}_2\text{Ph}$ ) have also been prepared by ligand exchanging reactions.  $\text{PhC}\equiv\text{N}$  is thermally displaced from  $\text{Tp}^*\text{Nb}(\text{CO})(\text{PhC}\equiv\text{CMe})(\text{PhC}\equiv\text{N})$  by  $\text{PhC}\equiv\text{CMe}$  to give  $\text{Tp}^*\text{Nb}(\text{CO})(\text{PhC}\equiv\text{CMe})_2$ .<sup>135</sup>

$\beta$ -Hydrogen abstraction from  $\eta^1$ -alkene ligands is another method to yield alkyne complexes.  $[\text{N}_3\text{N}]\text{Ta}(\text{C}_2\text{H}_2)$  is obtained, for example, from the reaction of  $[\text{N}_3\text{N}]\text{TaCl}_2$  with 2 equiv of  $\text{CH}_2=\text{CHMgBr}$ .<sup>110</sup>

Unique reversible migratory insertion/ $\beta$ -alkyl elimination (see *Migratory Insertion*) in Nb alkyl alkyne complexes has been reported.  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{CH}_2\text{R})(\text{PhC}\equiv\text{CMe})$  ( $\text{R} = \text{Me}$ , **32a**;  $\text{Et}$ , **32b**;  $\text{SiMe}_3$ , **32c**) undergo a thermally induced, first-order rearrangement, yielding methyl complexes  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{Me})(\text{PhC}\equiv\text{CCH}_2\text{R})$  (**32d-f**), respectively.  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{Pr}^i)(\text{PhC}\equiv\text{CEt})$  is in a 1:1 equilibrium with  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{Et})(\text{PhC}\equiv\text{CPr}^i)$ .  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{Et})(\text{PhC}\equiv\text{CEt})$  reacts with  $\text{PhC}\equiv\text{CMe}$  yielding  $\text{Tp}^*\text{Nb}(\text{Cl})(\eta^1\text{-CPh}=\text{CEt}_2)(\text{PhC}\equiv\text{CMe})$ , demonstrating that alkyl migration is a key step of the rearrangement. Kinetic and trapping studies indicate that the migratory insertion of the alkyl group onto the alkyne is the rate-determining step of the reactions.<sup>136</sup>

The *iso*-propyl complex  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{Pr}^i)(\text{PhC}\equiv\text{CMe})$  (**33a**) exhibits an unusual equilibrium between its  $\beta$ - (**33a- $\beta$** )

and minor  $\alpha$ -agostic (see *Agostic Bonding*) rotamer (**33a- $\alpha$** ) in solution ( $\Delta G^\ddagger_{193\text{ K}} = 11.4 \pm 0.6 \text{ kcal mol}^{-1}$ ;  $\Delta G^\circ_{193\text{ K}} = -0.53 \text{ kcal mol}^{-1}$ ) as the result of the restricted rotation about the Nb–C bond. This is a case that steric factors overcome the intrinsic electronic preference for the  $\beta$ -agostic structure. In solid state, the  $\beta$ -agostic isomer (**33a- $\beta$** ) is observed. This secondary alkyl complex thermally rearranges via a first-order reaction ( $\Delta G^\ddagger_{323\text{ K}} \approx 25.8 \text{ kcal mol}^{-1}$ ) to the linear,  $\alpha$ -agostic *n*-propyl isomer  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{Pr}^n)(\text{PhC}\equiv\text{CMe})$  (**33b**), which undergoes another first-order isomerization ( $\Delta G^\ddagger = 27.0 \text{ kcal mol}^{-1}$ ) to methyl complex (**33e**).<sup>137</sup> In the cyclopropyl complex  $\text{Tp}^*\text{Nb}(\text{Cl})(\text{cyclo-C}_3\text{H}_5)(\text{MeC}\equiv\text{CMe})$ , an unprecedented  $\alpha$ -C–C agostic interaction is observed to be preferred over both  $\alpha$ - and  $\beta$ -C–H agostic alternatives.<sup>138</sup>

### 5.2.2 Cyclopentadienyl Alkyne Complexes

Reduction of niobocene dichlorides in the presence of  $\text{RC}\equiv\text{CR}$  is one common path to niobocene alkyne complexes such as  $\text{Cp}_2\text{Nb}^{\text{V}}(\text{RC}\equiv\text{CR})\text{Cl}$ ,<sup>139–141</sup> and  $\text{Cp}'_2\text{Nb}^{\text{IV}}(\eta^2\text{-RC}\equiv\text{CR})$ .<sup>142</sup> Direct reactions of  $\text{Cp}'_2\text{Nb}^{\text{III}}\text{Cl}$  with the diynes or alkyne-alkenes give, for example,  $\text{Cp}'_2\text{NbCl}[\eta^2(\text{C},\text{C})\text{-PhC}\equiv\text{CCH}_2\text{CH}=\text{CH}_2]$ . Hydrogenation of the enyne-containing products occurs at the C=C bond using Pd/C as catalyst to give the alkyne complexes such as  $\text{Cp}'_2\text{NbCl}[\eta^2(\text{C},\text{C})\text{-PhC}\equiv\text{CCH}_2\text{CH}_2\text{CH}_3]$ .<sup>143</sup>

The deprotonation with BuLi at the propargylic site of the coordinated alkyne in  $\text{Tp}'\text{Nb}(\text{Cl})(\text{X})(\text{PhC}\equiv\text{CMe})$  ( $\text{X} = \text{Cl}, \text{OMe}$ ) followed by the reaction with MeI or  $\text{PhCH}_2\text{Br}$  affords the alkylated alkyne complexes  $\text{Tp}'\text{Nb}(\text{Cl})(\text{X})(\text{PhC}\equiv\text{CCH}_2\text{R})$  ( $\text{R} = \text{Me}, \text{CH}_2\text{Ph}$ ). Adding  $\text{PhCH}_2\text{Br}$  and MeI to the deprotonated  $\text{Tp}'\text{Nb}(\text{Cl})\text{(OMe)}(\text{PhC}\equiv\text{CCH}_2\text{Me})$  and  $\text{Tp}'\text{Nb}(\text{Cl})(\text{OMe})(\text{PhC}\equiv\text{CCH}_2\text{CH}_2\text{Ph})$ , respectively, gives 4:1 and 1:6 diastereomeric mixtures of  $\text{Tp}'\text{Nb}(\text{Cl})(\text{OMe})[\text{PhC}\equiv\text{CCHMe}(\text{CH}_2\text{Ph})]$ .<sup>144</sup>

### 5.2.3 Benzyne Complexes

Benzyne complexes contain  $\eta^2$ -benzyne, a moiety not stable in its free state, and are relatives of the alkyne complexes. Several methods have been used to prepare these complexes. Refluxing  $[\text{N}_3\text{N}]\text{TaCl}_2$  with PhLi affords  $[\text{N}_3\text{N}]\text{Ta}(\text{C}_6\text{H}_4)$ .<sup>110</sup> Thermolysis of the methyl phenyl complex  $\text{Cp}^*\text{TaMe}(\text{Ph})(\eta^4\text{-butadiene})$  gives the benzyne complex  $\text{Cp}^*\text{Ta}(\eta^4\text{-butadiene})(\eta^2\text{-C}_6\text{H}_4)$ , the first example of the parent benzyne complex bearing a metallocene-like  $\text{MCp}(\text{diene})$  fragment.<sup>145</sup> The  $\eta^2$ -benzyne complex  $\text{CpTa}(\eta^2\text{-C}_6\text{H}_4)(\text{PMe}_3)(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)$  (**34**), an analogue of tantalocenes, is prepared from  $\text{CpTaPh}_2(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)$  and excess  $\text{PMe}_3$ . In a striking demonstration of the electronic influence of the carborane ligand, the properties of (**34**) contrast dramatically with those of normal metal ( $\eta^2$ -benzyne) complexes. (**34**) is air-stable, does not undergo coupling with unsaturated substrates such as acetone, and is not protonated by MeOH.<sup>146</sup>

The mechanism of  $\text{H}_2$  addition to benzyne complex  $\text{Cp}^*_2\text{Ta}(\eta^2\text{-C}_6\text{H}_4)\text{H}$  has been investigated by parahydrogen-induced polarization (PHIP). This hydrogenation (see *Hydrogenation*) gives  $\text{Cp}^*_2\text{Ta}(\text{Ph})\text{H}_2$ , which then adds another equiv of  $\text{H}_2$  to give  $\text{Cp}^*\text{TaH}_3$ . Addition of *para*- $\text{H}_2$  leads to strong polarization in the hydride resonances of  $\text{Cp}^*_2\text{Ta}(\text{Ph})\text{H}_2$ , providing evidence for a 16-electron intermediate in the reaction. In the formation of  $\text{Cp}^*\text{TaH}_3$  with *para*- $\text{H}_2$ , polarization of the hydride resonances is observed. D-labeling studies also indicate  $\text{H}_2$  addition to the 16-electron monohydride ' $\text{Cp}^*_2\text{TaH}$ ' intermediate. This work provides definitive evidence of pairwise, concerted  $\text{H}_2$  oxidative addition to two  $\text{Ta}^{\text{III}}$  complexes in the hydrogenation reactions.<sup>147</sup>

### 5.3 $\eta^2$ -Acyls, $\eta^2$ -Iminoacryls, and Related Complexes

The  $\eta^2$ -acyls,  $\eta^2$ -iminoacryls and related complexes originate from the migratory insertion (see *Migratory Insertion*) of  $\text{C}\equiv\text{O}$  or isocyanides  $\text{C}\equiv\text{NR}$  into a metal–alkyl bond. These complexes are of interest mainly because of their relevance to catalytic CO reduction and the C–C bond formation in Fischer–Tropsch (see *Fischer–Tropsch Process*) reactions.

A large number of  $\eta^2$ -iminoacyl complexes have been reported. A series of  $\eta^2$ -iminoacyl derivatives  $\text{CpMX}(\text{NXyl})[\eta^2\text{-C(R)=NXyl}]$  ( $\text{X} = \text{Cl}, \text{R}$ ) are prepared by reactions of chloro alkyl or dialkyl imides  $\text{CpMX(R)}(\text{NXyl})$  with 1 equiv of  $\text{CNXyl}$ . Reaction of  $\text{Cp}^*\text{TaRMe}(\text{NXyl})$  with  $\text{CNXyl}$  involves the migration of alkyl or Me group, giving a mixture of  $\text{Cp}^*\text{TaMe}(\text{NXyl})[\eta^2\text{-C(R)=NXyl}]$  and  $\text{Cp}^*\text{TaR}(\text{NXyl})[\eta^2\text{-C(Me)=NXyl}]$ .<sup>22</sup> The following complexes are prepared similarly:  $\text{Cp}^*\text{Ta}(\text{CH}_2\text{SiMe}_3)(\text{CHSiMe}_3)[\eta^2\text{-C}(\text{CH}_2\text{SiMe}_3)=\text{NXyl}]$ ,<sup>120</sup>  $\text{Cp}^*\text{Ta}(\eta^2\text{-MeCNR})(\eta^2\text{-PhCCPh})\text{Me}$  ( $\text{R} = \text{Bu}^t, \text{Me}$ ),<sup>148</sup>  $\text{Cp}^*\text{TaR}(\eta^2\text{-CR=NXyl})\text{(NXyl)}$  ( $\text{R} = \text{Et}, \text{Pr}^n$ ),<sup>149</sup> and  $\text{Cp}'_2\text{Ta}[\eta^2\text{-Bu}^t\text{N}=\text{CCH}_2\text{B}(\text{C}_6\text{F}_5)_3]$ .<sup>150</sup>

The carborane (*see Carborane*) complex  $(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)\text{-CpTaMe}_2$  is found to undergo insertion reactions with isocyanides under UV-visible irradiation to afford both isomers of  $(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)\text{CpTaMe}[\eta^2\text{-C}, N\text{-C(=NR)Me}]$  ( $R = \text{Bu}^t$ , Xyl). The isomers interconvert under heat. The diphenyl complex  $(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)\text{CpTaPh}_2$  generally reacts at elevated temperatures to give only one isomer of  $(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)\text{CpTaPh}[\eta^2\text{-C}, N\text{-C(=NXyl)Ph}]$ .<sup>151</sup>

Reactions of  $\text{Cp}^*\text{TaMe}_2\text{X}_2$  [ $\text{X}_2 = \text{Cl}_2$ ,  $(\text{SCH}_2\text{CH}_2)_2\text{O}$ ] with 1 equiv of isocyanides occur with double migration of Me, giving imine complexes  $\text{Cp}^*\text{TaX}_2(\eta^2\text{-Me}_2\text{CNR})$  [ $R = \text{Xyl}$ , 2,4,6-Me<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>,  $\text{X}_2 = \text{Cl}_2$ ;<sup>152,153</sup>  $R = \text{Xyl}$ ,  $\text{X}_2 = (\text{SCH}_2\text{CH}_2)_2\text{O}$ ].<sup>29</sup> Mono- and dimethylated imines  $\text{Cp}^*\text{TaCl}_n\text{Me}_{2-n}(\eta^2\text{-XylN=CMe}_2)$  were similarly prepared. They react with second equiv of isocyanide to give imido alkenylamido species  $\text{Cp}^*\text{TaX(=NXyl)(NR'CMe=CMe}_2)$  ( $X = \text{Cl}$ , Me;  $R' = \text{Xyl}$ , 2,4,6-Me<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>, **35**). Reactions of **(35)** with third equiv of  $R''\text{NC}$  ( $R'' = \text{Xyl}$ , 2,4,6-Me<sub>3</sub>-C<sub>6</sub>H<sub>2</sub>,  $\text{Bu}^t$ ) afford  $\eta^2$ -imino acyl compounds  $\text{Cp}^*\text{TaX(=NXyl)(}\eta^2\text{-NR''=CCMe}_2\text{CMe=NR')}$ .<sup>154</sup> It is interesting to note that insertion of CNXyl into the Ta–Me bond in  $\text{Cp}^*\text{Ta(=NBu}^t)\text{Me(NR}_2)$  ( $R = \text{Ph}$ , SiMe<sub>3</sub>) gives  $\text{Cp}^*\text{Ta(=NBu}^t)(\text{NR}_2)[\eta^1\text{-C(Me)=NXyl}]$ , and CNXyl inserts into the Ta–N bond in  $\text{Cp}^*\text{Ta(=NBu}^t)\text{Me(NMeR)}$  ( $R = \text{H}$ , Me) to give  $\text{Cp}^*\text{Ta(=NBu}^t)\text{Me}[\eta^2\text{-C(NRMe)=NXyl}]$ .<sup>155</sup> When the reaction of  $\text{Cp}^*\text{TaMe}_2\text{Cl}_2$  with CNXyl is carried out in the presence of a trace amount of H<sub>2</sub>O, a cyclic  $\eta^2$ -amido-carbene species  $\text{Cp}^*\text{TaCl}_3[\eta^2\text{-N(Xyl)CMe}_2\text{CNHR}]$  was produced.<sup>154</sup>  $\eta^2$ -Iminoacyl complexes  $\text{Cp}^*\text{Ta(NBu}^t)(\text{NHBu}^t)\{\eta^2\text{-C(Me)=NR}\}$  react with one equiv of CNXyl to give the double insertion imine- $\eta^2$ -iminoacyl complexes  $\text{Cp}^*\text{Ta(NBu}^t)(\text{NHBu}^t)\{\eta^2\text{-C[C(Me)=NR]=NR}\}$ , which when heated undergo an intramolecular H migration to yield  $\eta^2$ -diamidoalkenes  $\text{Cp}^*\text{Ta(NBu}^t)\{\eta\text{-NBu}^t\text{-C(NHR)=C(Me)-}\eta\text{-NR}\}$ .<sup>156</sup>

In the reactions of  $(\text{Me}_2\text{S})_2\text{Cl}_4\text{Ta}_2(\mu\text{-Me}_2\text{S})(\mu\text{-Cl})_2$  with formamidinate anions,  $[\text{ArNC(H)NPh}]^-$ , C–N bond cleavage is observed. The reaction of  $[\text{PhNC(H)NPh}]^-$  ( $\text{DPhF}^-$ ) with  $(\text{Me}_2\text{S})_2\text{Cl}_4\text{Ta}_2(\mu\text{-Me}_2\text{S})(\mu\text{-Cl})_2$  and Zn yields the CNPh-containing compound  $(\eta^2\text{-DPhF})_2\text{Ta}(\mu\text{-NPh})(\mu\text{-}\eta^2\text{-CNPh})\text{Ta}(\eta^2\text{-DPhF})_2$ . When  $[\text{ToINc(H)NTol}]^-$  ( $\text{DTolF}^-$ ) and Na/Hg are used, the isolated product is  $(\eta^2\text{-DTolF})\text{Ta}(\mu\text{-NTol})(\mu\text{-}\eta^2\text{-CNTol})(\mu\text{-DTolF})_2\text{Ta}(\eta^2\text{-DTolF})$ . In the absence of a reducing agent, the reaction with LiDTolF produces  $\text{Cl}_2(\eta^2\text{-DTolF})\text{Ta}(\mu\text{-NTol})(\mu\text{-}\eta^2\text{-HCNTol})\text{Ta}(\eta^2\text{-DTolF})_2$  in which a tolylformimidoyl fragment ( $\text{HCNTol}^{3-}$ ) binds to the Ta atoms through both C and N atoms in an  $\eta^2, \eta^2$  mode.<sup>157</sup>

#### 5.4 CO<sub>2</sub>, Isocyanate, and Related Complexes

Olefin-hydride complexes such as  $\text{Cp}'_2\text{Nb(H)}(\eta^2\text{-H}_2\text{C=CH}_2)$  react with CO<sub>2</sub> to afford, for example,  $\text{Cp}'_2\text{Nb(Et)}(\eta^2\text{-CO}_2)$  (**36**). When  $\text{B(C}_6\text{F}_5)_3$  is added to **(36)**, the adduct  $\text{Cp}'_2\text{Nb(Et)}[\eta^2\text{-CO}_2\text{-B(C}_6\text{F}_5)_3]$  is yielded

in the first step, which subsequently evolves to give the oxo-alkyl complexes  $\text{Cp}'_2\text{Nb(Et)}[\text{O-B(C}_6\text{F}_5)_3]$  with the loss of CO.<sup>86</sup> Upon heating, the coordinated CO<sub>2</sub> ligand in  $(\text{MeC}_5\text{H}_4)_2\text{Nb}(\eta^2\text{-CO}_2)(\text{CH}_2\text{R})$  ( $R = \text{SiMe}_3$ ,  $\text{Bu}^t$ , Ph, H) splits, giving  $(\text{MeC}_5\text{H}_4)_2\text{Nb(=O)}(\text{CH}_2\text{R})$  and CO.<sup>158</sup> As in the formation of **(36)**, reactions of CS<sub>2</sub> with  $\text{Cp}'_2\text{Nb(H)}(\eta^2\text{-RHC=CH}_2)$  ( $R = \text{H}$ , Ph) afford  $\text{Cp}'_2\text{Nb}(\eta^2\text{-CS}_2)(\text{CH}_2\text{CH}_2\text{R})$ . Interaction of  $\text{Cp}'_2\text{NbX}(\eta^2\text{-CS}_2)$  ( $X = \text{Cl}$ , carboxylate) with alkynes  $\text{R}'\text{C}\equiv\text{CR}'$  bearing electron-withdrawing groups gives 1,3-dithiol-2-ylidene complexes

Nb and Ta complexes with other  $\eta^2$ -ligands such as  $\eta^2\text{-COS}$ ,  $\eta^2\text{-OCN}$  and  $\eta^2\text{-COTe}$  have also been reported.  $(\text{Cp}'_2\text{NbCl})_2$  reacts with phenyl isocyanate  $\text{PhN=C=O}$  to give the adduct  $\text{Cp}'_2\text{NbCl}(\eta^2\text{-N,C-OCNPh})$ . Similar dinuclear adducts are obtained from the reactions of  $(\text{Cp}'_2\text{NbCl})_2$  with 1,3- and 1,4-phenylenedi-isocyanate.<sup>160</sup>

#### 5.5 Ketene and Ketenimine Complexes

Complexation of the ketene C=O bonds in, for example,  $\text{Cp}'_2\text{Nb(Cl)}[\eta^2\text{-O=C=CMe}_2]$  (**37**) is usually observed. Ketene complexes are prepared from coordination of ketenes to  $\text{Cp}'_2\text{NbCl}$ <sup>161</sup> or deprotonation of  $\eta^2$ -acyl in  $\text{Cp}'_2\text{NbCl}(\eta^2\text{-O=C-CHEtPh})$ .<sup>162</sup> Treatment of **(37)** with  $(\text{Ph}_3\text{C})(\text{BF}_4)$  leads to  $\gamma$ -hydride abstraction to give  $\eta^2$ -enacyl salts  $[\text{Cp}'_2\text{Nb(Cl)}(\eta^2\text{-OCCMe=CH}_2)](\text{BF}_4)$ .<sup>163</sup> The ketene complex  $\text{Cp}'_2\text{Nb(H)}(\eta^2\text{-C,O-O=C=CPh}_2)$  reacts with MeCN or  $\text{Bu}^t\text{NC}$  to yield isocyanate and  $\text{Cp}'_2\text{Nb(H)}(\text{=C=CPh}_2)$ .<sup>164</sup> A synthetic strategy involving sequential hydride abstraction and proton abstraction has been developed to convert the  $\eta^2\text{-C, O}$  ketene ligand in  $\text{Cp}'_2\text{Nb(Cl)}(\eta^2\text{-OC=CRET})$  ( $R = \text{Ph}$ , Et) into a vinylketene ligand  $\eta^2\text{-OC=C(R)CH=CH}_2$ . These are the first vinylketene complexes exhibiting the  $\eta^2\text{-C,O}$  bonding mode.<sup>165</sup>

Ketenimine complexes such as  $\text{Cp}'_2\text{NbCl}(\eta^2\text{-C,N-Ph}_2\text{C=C=NPh})$  (**38**) reacts with  $\text{HBF}_4\cdot\text{OEt}_2$  to give  $\eta^2$ -iminoacyl  $[\text{Cp}'_2\text{NbCl}(\eta^2\text{-C,N-Ph}_2\text{CHC=NPh})]^+ \text{BF}_4^-$ .<sup>166</sup> Reduction of **(38)** with Na/Hg yields  $\text{Cp}'_2\text{Nb}^{\text{IV}}(\eta^2\text{-C,N-Ph}_2\text{C=C=NPh})$ , which is oxidized by  $\text{Cp}_2\text{Fe}^+$  in the presence of nitriles or isonitriles L to give  $[\text{Cp}'_2\text{Nb}(\eta^2\text{-C,N-Ph}_2\text{C=C=NPh})(\text{L})]^+$ , cationic derivatives of **(38)**.<sup>167</sup>

#### 5.6 Ketone, Aldehyde, Imine, and Related Complexes

Ketone and aldehyde complexes have been prepared from deprotonation of the relatively strong C–H acid  $\text{Cp}'_2\text{Nb(Cl)}(\text{OMe})^+$  to give  $\text{Cp}'_2\text{Nb(Cl)}(\eta^2\text{-OCH}_2)$ ,<sup>162</sup> reaction of  $\text{Nb(NPr}^i\text{Ar)}_3\text{Cl}$  ( $\text{Ar} = 3,5\text{-Me}_2\text{-C}_6\text{H}_3$ ) with  $\text{O=CPh}_2$  to yield  $\text{Nb}(\eta^2\text{-OCPh}_2)(\text{NPr}^i\text{Ar})_3$ ,<sup>168</sup> and double migration of alkyl groups in  $\text{Ta}\{p\text{-Bu}^t\text{-calix[4]-(OMe)(O)}_3\}\text{R}_2$  ( $R = \text{Me}$ , Bz,  $p\text{-MeC}_6\text{H}_4$ ,  $\eta^3$ -allyl **39**) in their reactions with CO to form  $(\text{calix[4]OMe})\text{Ta}(\eta^2\text{-OCR}_2)$ . Reactions of **(39)** with

Bu'NC yields related imine complexes (calix[4]OMe)Ta( $\eta^2$ -Bu'N=CR<sub>2</sub>).<sup>169,170</sup> Although butadiene is  $\pi^2, \eta^4$ -bonded to the metal in Ta{*p*-Bu'-calix[4]-(OMe)(O)<sub>3</sub>}( $\eta^4$ -C<sub>4</sub>H<sub>6</sub>), it behaves as if it were  $\eta^4, \sigma^2$ - $\pi$  bonded in the migratory insertion reaction with Bu'NC to afford an  $\eta^2$ -imine derivative.<sup>169</sup>

The  $\eta^2$ -formaldehyde complex Cp'<sub>2</sub>Nb(Cl)( $\eta^2$ -CH<sub>2</sub>O) undergoes facile Na/Hg reduction to produce the radical Cp'<sub>2</sub>Nb<sup>IV</sup>( $\eta^2$ -CH<sub>2</sub>O), which then reacts with H<sub>2</sub> to give Cp'<sub>2</sub>Nb<sup>V</sup>(=O)Me. In the presence of added alcohol, this reduction yields diamagnetic hydride Cp'<sub>2</sub>Nb(H)( $\eta^2$ -CH<sub>2</sub>O).<sup>171</sup>

Telluroformaldehyde complex Cp'\*<sub>2</sub>Ta( $\eta^2$ -TeCH<sub>2</sub>)H (**40**) is prepared by the PMe<sub>3</sub>-catalyzed addition of Te to the Ta=CH<sub>2</sub> in Cp'\*<sub>2</sub>Ta(=CH<sub>2</sub>)H. (**40**) is converted to its more stable isomer Cp'\*<sub>2</sub>Ta(=Te)CH<sub>3</sub> under heating.<sup>84</sup>

### 5.7 $\eta^2$ -Arene, $\eta^2$ -Pyridine, and Related Complexes

In contrast to some  $\eta^2$ -C,C-heterocycles containing other metals, Nb and Ta prefer to bind N-heterocycles in the  $\eta^2$ -C,N mode. The very first complex of this type, (silox)<sub>3</sub>Ta( $\eta^2$ -N,C-py), was reported by Wolczanski and coworkers in 1988.<sup>172</sup> Its Nb analogs (silox)<sub>3</sub>Nb( $\eta^2$ -N,C-L) (L = py, 4-picoline, 3,5-lutidine) are prepared by reduction of (silox)<sub>3</sub>NbCl<sub>2</sub> with Na/Hg in pyridine or 4-picoline.<sup>173–175</sup> Heating the pyridine and lutidine adducts leads to the cleavage of the C=N bond. Similar reduction of (silox)<sub>2</sub>TaCl<sub>2</sub>(NR<sub>2</sub>) (NR<sub>2</sub> = pyrrolidide, piperidide) with Na/Hg in pyridine gives (silox)<sub>2</sub>Ta(NR<sub>2</sub>)( $\eta^2$ -N,C-py), which react with MeNH<sub>2</sub> to yield imides (silox)<sub>2</sub>Ta(NR<sub>2</sub>)(=NMe).<sup>175</sup> Reduction of (ArO)<sub>3</sub>TaCl<sub>2</sub>( $\eta^1$ -N-L) (L = quinoline, 6-methylquinoline; Ar = 2,6-Pr<sup>i</sup>-C<sub>6</sub>H<sub>3</sub>) leads to an  $\eta^1$ (N)  $\rightarrow$   $\eta^2$ (N,C) bonding rearrangement to give (ArO)<sub>3</sub>Ta( $\eta^2$ -N,C-L).<sup>176</sup> Reaction of NbCl<sub>4</sub>(THF)<sub>2</sub> with LiNCy<sub>2</sub> leads to the formation of imine Nb( $\eta^2$ -N,C-CyN=C<sub>6</sub>H<sub>10</sub>)(NCy<sub>2</sub>)<sub>2</sub>Cl containing one metallated cyclohexyl ring.<sup>177</sup>

## 6 METALLACYCLIC COMPLEXES

Metallacyclic (*see Metallacycle*) complexes of niobium and tantalum play an important role in understanding several catalytic and stoichiometric transformations of organic compounds. Some group 5 metallacycles are formed from the inter- or intramolecular hydride abstraction reactions. Most of the Nb and Ta metallacycles are prepared, however, from reductive coupling (*see Reductive Coupling*) of unsaturated organic substrates. To be included in this section, the metallacyclic ligand must have at least one M–C bond.

### 6.1 Metallacyclobutanes and Other Four-member Rings

Metallacyclobutanes are important intermediates in alkene metathesis (*see Alkene Metathesis*). Many Ta and Nb alkylidene complexes do not readily afford metathesis products upon reactions with alkenes. These reactions often lead to the formation of metallacyclobutanes. The alkylidene Ta(=CHSiMe<sub>3</sub>)[NCN]Cl(OBu') is prepared from the metathesis of Ta(=CHBu')(NCN)Cl(OBu') (**24a**, Section 4.1) with CH<sub>2</sub>=CHSiMe<sub>3</sub>, and yet it does not undergo further metathesis with ethene. This reaction instead leads to the formation of the tantalacyclobutane complex (**41**).<sup>116</sup> Similarly, the dialkoxides Ta(=CHBu')[CNN](OBu')<sub>2</sub> (**30b**) reacts with ethene to afford the tantalacyclobutane (**31a**) (Section 4.2).<sup>123</sup> (**30b**) and (**31a**) initiate ring-opening metathesis polymerization (*see Ring Opening Metathesis Polymerization Reactions*) of strained cyclic olefins such as dicyclopentadiene and norbornene. Metathesis of (**31a**) with propene and styrene gives substituted tantalacyclobutane complexes (**31b–c**). Insertion of Bu'NC into the Ta–C bonds in (**31a–c**) affords Ta[C(=NBu')CH<sub>2</sub>CHRCH<sub>2</sub>-1,4][CNN](OBu')<sub>2</sub> (R = H, Me, Ph, **42a–c**).<sup>178</sup>

Ta alkylidenes (RCH<sub>2</sub>)<sub>3</sub>Ta(L)=CHR and RCH<sub>2</sub>Ta(L)<sub>2</sub>(=CHR)<sub>2</sub> (R = SiMe<sub>3</sub>, L = PMe<sub>3</sub>) react with phenylsilanes H<sub>2</sub>SiR'Ph (R' = Me, Ph) and (PhSiH<sub>2</sub>)<sub>2</sub>CH<sub>2</sub> to give bis(silyl)-substituted alkylidene complexes (RCH<sub>2</sub>)<sub>3</sub>Ta=CR(SiHR'Ph) and novel metallasilacyclobutadiene (**43a**) and metalladisilacyclohexadiene complexes (**44**). Reactions of the mixed-ligand trimethylsilylmethyl neopentylidene complex RCH<sub>2</sub>Ta(L)<sub>2</sub>(=CHBu')<sub>2</sub> with H<sub>2</sub>SiMePh also yield a metallasilacyclobutadiene complex (**43b**).<sup>179,180</sup>

## 6.2 Metallacyclopentanes, Metallacyclopentadienes, and Other Five-member Rings

Metallacyclopentanes are of considerable importance as intermediates in catalytic alkene dimerization (see *Oligomerization & Polymerization by Homogeneous Catalysis*).

The tantalacyclopentane  $\text{Cp}^*(\text{DippN}=\text{Ta})[\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2]$  (45) and tantalacyclopentadiene  $\text{Cp}^*(\text{DippN}=\text{Ta})[\text{CPh}=\text{CPh}=\text{CPh}=\text{CPh}]$  are obtained when  $\text{Cp}^*(\text{DippN}=\text{Ta})[\text{Si}(\text{SiMe}_3)_3]\text{H}$  (Dipp = 2,6- $\text{Pr}_2\text{-C}_6\text{H}_3$ ) is treated with ethylene and diphenylacetylene, respectively.<sup>181</sup>  $\text{Cp}^*\text{Ta}(=\text{NDipp})\text{Cl}_2$  reacts with excess  $\text{EtMgCl}$  in the presence of  $\text{CH}_2=\text{CH}_2$ , giving (45) as well. (45) undergoes exchange with  $\text{C}_2\text{D}_4$  to give (45- $\text{d}_8$ ), and double CO insertion to yield a cyclic diacyl complex in which CO has inserted into both of the metallacyclic Ta–C bonds.<sup>182</sup>

Insertion of ethylene and 2-butyne into the Ta benzyne bond of  $\text{Cp}^*\text{Ta}(\eta^4\text{-butadiene})(\eta^2\text{-C}_6\text{H}_4)$  affords the metallacycles (46a) and (46b), respectively. Similar insertion of acetonitrile and carbon dioxide gives metallacycles (46c) and (46d).<sup>145</sup>

Alkylation of  $\text{Cp}^*\text{Cp}'\text{TaCl}_2$  with  $\text{LiCH}_2\text{CMe}_2\text{Ph}$  gives the benzocyclic complex  $\text{Cp}^*\text{Cp}'\text{Ta}(\text{H})(\eta^2\text{-CH}_2\text{-CMe}_2\text{-o-C}_6\text{H}_4)$  (47). In comparison, the alkylation with  $\text{Mg}(\text{CH}_2\text{Ph})_2(\text{THF})_2$  or  $\text{LiCH}_2\text{R}$  ( $R = \text{SiMe}_3$ ,  $\text{Bu}^t$ ) gives bis( $\mu$ -alkylidene) complexes  $(\text{Cp}^*\text{Cp}'\text{Ta})_2(\mu\text{-CHR})_2$  ( $R = \text{Ph}$ ,  $\text{SiMe}_3$ ,  $\text{Bu}^t$ ).<sup>183</sup>

Thermolysis of  $(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)\text{CpTaPh}_2$  (48) in the presence of alkynes and 1,4-diphenylbutadiyne leads to the formation of the five-membered metallacycles (49a–b). (49a) reacts with excess  $(\text{Et}_2\text{C}_2\text{B}_4\text{H}_4)\text{CpTaPh}_2$ , giving a bis-insertion product (50).<sup>184</sup> Reaction of (48) with excess styrene  $\text{PhCH}=\text{CH}_2$  results in a novel triple-insertion process in which styrene units are added to both ortho positions of an aryl ligand and to the central B atom of the  $\text{C}_2\text{B}_3$  ring in (51).<sup>184</sup>

e.g.,  $R = R' = \text{Et, Ph}$  (49a)  
 $R = \text{Ph}$ ,  $R' = \text{PhC}\equiv\text{C-}$  (49b)

$\text{Tp}^*\text{NbCl}_2(\text{PhC}\equiv\text{CR})$  ( $R = \text{Me}$ , 52a;  $\text{Ph}$ , 52b) reacts with allyl Grignard giving the five-membered niobacycles  $\text{Tp}^*(\text{Cl})\text{Nb}(=\text{CPh-CR}=\text{CH-CHMe})$ .<sup>185</sup> When (52a) is treated with  $\text{EtMgCl}$ , the formal dehydrogenation of an ethyl group gives the alkyne-coupled product  $\text{Tp}^*\text{NbEt}(=\text{CPh-CMe}=\text{CHCH}_2)$ .<sup>133</sup>

Protonation of the 3e-alkyne- $\eta^2(3e)$ -nitrile complex  $\text{Tp}^*\text{Nb}(\text{CO})(\text{PhC}\equiv\text{CMe})(\text{EtC}\equiv\text{N})$  with  $\text{HBF}_4$  induces nitrile/alkyne coupling to give  $\text{Tp}^*\text{NbF}(=\text{CPh-CMe}=\text{CPhNH})$ .

via  $[\text{Tp}^*\text{Nb}(\text{CO})(\eta^2\text{-CPh=NH})(\text{PhC}\equiv\text{CMe})](\text{BF}_4)$ . Protonation of  $\text{Tp}^*\text{Nb}(\text{CO})(\text{PhC}\equiv\text{CMe})_2$  with  $\text{HBF}_4$  leads to the niobacycle  $\text{Tp}^*\text{NbF}[=\text{CPh-CMe=C(-CMe=CHPh)O}]$  in which CO is included in the alkyne coupling reaction.<sup>135</sup>

Similar five-membered oxaniobiacycles  $\text{Tp}^*\text{Nb}(\text{OMe})(=\text{CPh-CR=CMe-O})$  ( $\text{R} = \text{Me}, \text{Et}$ ) and  $\text{Tp}^*\text{Nb}(\text{OMe})(=\text{CPh-CEt=CPh-O})$  are prepared from the regioselective coupling of the coordinated alkyne with an acetyl or benzoyl group in the reactions of  $\text{Tp}^*\text{NbMe}(\text{OMe})(\text{PhC}\equiv\text{CR})$  and  $\text{Tp}^*\text{NbPh}(\text{OMe})(\text{PhC}\equiv\text{CEt})$  with CO.<sup>186</sup>

Reaction of  $\text{Cp}^*\text{Ta}(\text{CH}_2\text{SiMe}_3)_2(=\text{CHSiMe}_3)$  with 2,6-Me<sub>2</sub>-C<sub>6</sub>H<sub>3</sub>OH leads to H abstraction from the methyl group in Ta-(O-2,6-Me<sub>2</sub>C<sub>6</sub>H<sub>3</sub>), giving the cyclic alkyl-alkoxo derivative  $\text{Cp}^*\text{Ta}(\text{CH}_2\text{SiMe}_3)_2\{\eta^2\text{-O(2-CH}_2\text{-6-MeC}_6\text{H}_3)\}$  with the elimination of SiMe<sub>4</sub>.<sup>120</sup>

$\text{Cp}'_2\text{Ta}[\text{CH}_2\text{B}(\text{C}_6\text{F}_5)_2](\mu\text{-H})(\text{Me})$ , generated via treatment of  $\text{Cp}'_2\text{Ta}(=\text{CH}_2)\text{Me}$  with  $\text{HB}(\text{C}_6\text{F}_5)_2$ , undergoes irreversible methane loss in the presence of an excess of  $\text{MeC}\equiv\text{CMe}$  and  $\text{PhC}\equiv\text{CH}$ , giving the tantalum-3-boratacyclopentene compounds (**53a-b**). The kinetic product (**53b**) thermally rearranges to the thermodynamic product (**53c**).<sup>187</sup>

$(\text{silox})_3\text{TaH}_2$  thermally cyclometallates to  $(\text{silox})_2(\text{H})\text{-TaOSiBu}^t_2\text{CMe}_2\text{CH}_2$ , but is reconstituted with H<sub>2</sub>. Reduction of  $(\text{silox})_3(\text{H})\text{TaI}$  with Na/Hg in THF produces a ring-opened THF complex  $(\text{silox})_3\text{Ta}(\text{H})[\mu\text{-CH}_2(\text{CH}_2)_3\text{O-}]\text{-Ta}(\text{H})(\text{silox})_3$ .<sup>188</sup>

### 6.3 Other Metallacycles

Reaction of  $\text{Cp}^*\text{TaCl}_3[\eta^2\text{-C}_6\text{H}_4(2\text{-CH}_2\text{NMe}_2)]$  with 1 and 3 equiv of  $\text{Li}[2\text{-(Me}_2\text{NCH}_2)\text{-C}_6\text{H}_4]$  causes successive  $\beta$ -H abstraction at one of the methylamino groups, giving the cyclometallated (**54**) and alkyldiene (**55a**). Similarly, the reactions of (**54**) with 2 equiv of  $\text{LiNMe}_2$  and 1 equiv of  $\text{LiN}(\text{SiMe}_3)_2$  yield the tantalacycloalkyldienes (**55b**) and (**55c**), respectively.<sup>189</sup>

On standing at room temperature, the d<sup>0</sup> carbonyl complex  $\text{Cp}^*(\text{ArN=})\text{Ta}(\text{CO})[\text{Si}(\text{SiMe}_3)_3]\text{H}$  transforms into the tantalacycle (**56**).<sup>190</sup>

Photolysis of  $\text{Ta}(\text{OAr})_2(\text{CH}_2\text{SiMe}_3)_3$  ( $\text{Ar} = 2,6\text{-Ph}_2\text{-3,5-R}_2\text{-C}_6\text{H}_3$ ;  $\text{R} = \text{H}, \text{Ph}, \text{Me}, \text{Pr}^i$ ) generates alkyldienes  $\text{Ta}(\text{OAr})_2(=\text{CHSiMe}_3)(\text{CH}_2\text{SiMe}_3)$ , which undergo intramolecular cyclometallation (see *Cyclometallation*) of the aryloxo ligand, through the addition of an aromatic C-H bond to the Ta alkyldiene, to form (**57**).<sup>53</sup>

The cation complex  $[(s\text{-trans-}\eta^4\text{-butadiene})\text{TaCp}^*\text{Cp}]^+$  (**58**) was found to react with ketones such as acetone and adamantanone, as well as 1-cyanoadamantane to yield seven-membered 2-tantalatetrahydrooxepine (**59a-b**).

and 2-tantala-3,6-dihydro-2H-azepine (**59c**) cation complexes, respectively. Activation of (**58**) with methylalumoxane gives an active ethene polymerization (see *Oligomerization & Polymerization by Homogeneous Catalysis*) catalyst.<sup>191</sup>

In the course of the model studies of hydrodenitrogenation (HDN) reactions (See Section 9.5), thermolysis of ( $\eta^2$ -*N,C*-2,4,6-Bu<sub>3</sub>-NC<sub>5</sub>H<sub>2</sub>)Ta(OAr)<sub>2</sub>X (**60**) leads to migration of alkyl (Me, Et, Pr<sup>n</sup>, Bu<sup>n</sup>) and aryl ligands from metal to ligand, giving the ring-opened compounds (**61**).<sup>192</sup> The reaction of (**60-Cl**) (X = Cl) with hydride LiBEt<sub>3</sub>H similarly affords the C–N bond scission product (**61-H**) (X = H).<sup>193</sup> (**61-Me**) undergoes thermal decomposition in THF to give the metallapyridine (**62**) through elimination of Bu<sup>t</sup>CH=CH<sub>2</sub>. (**62**) reacts with electrophiles such as isocyanates and carbodiimides to afford insertion products (**63**) and (**64**).<sup>194</sup>

Ta(OAr)<sub>2</sub>Cl<sub>2</sub>(H)(PMe<sub>2</sub>Ph)<sub>2</sub> (Ar = 2,6-Pr<sup>i</sup><sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) reacts with RNC (R = Ar, Xyl, Bu<sup>t</sup>) to produce phosphine adduct  $\eta^2$ -iminoformyl complexes (**65**). Further reactions of XylNC with (**65-Xyl**) (R = Xyl) and of Bu<sup>t</sup>NC with (**65-Bu<sup>t</sup>**) (R = Bu<sup>t</sup>) yield the ylide derivative (**66a**) and (**66b**), respectively. Ta(OAr')<sub>2</sub>Cl<sub>2</sub>(H)(PMePh)<sub>2</sub> (Ar' = 2,6-Bu<sup>t</sup><sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) reacts with RNC (R = Xyl, Bu<sup>t</sup>) to produce monocyclometallated complex (**67**) in which three H atoms have been transferred to the isocyanide substrate to give the amido ligand.<sup>31</sup>

Reduction of Nb(OAr)<sub>3</sub>Cl<sub>2</sub> (Ar = 2,6-Pr<sup>i</sup><sub>2</sub>-C<sub>6</sub>H<sub>3</sub>) by Na/Hg in the presence of donor ligands leads to dehydrogenation of the *ortho*-isopropyl group of an aryloxy group yielding  $\eta^2$ - $\alpha$ -methylvinyl complex (**68**). The metallacyclopropane ring in (**68-THF**) (L<sub>n</sub> = THF) undergoes ring expansion (coupling of the olefin) with unsaturated substrates such as Ph<sub>2</sub>C=O and PhC $\equiv$ CR (R = H, Ph) to give 2-oxaniobacyclopentane (**69a**) and niobacyclopentene derivatives (**69b**).<sup>195</sup>

Bridging alkylidynes (cb)<sub>2</sub>M( $\mu$ -CSiMe<sub>3</sub>)<sub>2</sub>M(cb)<sub>2</sub> (**70**) react rapidly with isocyanide XylNC to give bridging amidoalkyne complexes (**71**) through coupling of the isocyanide with one of the alkylidyne bridges in (**70**).<sup>196</sup> Similar coupling of alkynes with (**70**) yields nonplanar six-membered dimetallacycles (**72**).<sup>197</sup>

$L_n = \text{Py}_2, (\text{Bu}^i\text{NC})_2, \text{THF}; \text{X} = \text{OAr}$

$L_n = \text{PMe}_2\text{Ph}; \text{X} = \text{Cl}$

## 7 $\pi$ -COMPLEXES OF CARBOCYCLIC, ENE, ENYL AND RELATED LIGANDS

### 7.1 $\eta^3$ -Complexes

The stable bis(allyl)tantalum complex  $\text{Cp}^*\text{Ta}(\eta^3\text{-1-phenylallyl})_2$  obtained from the reaction of  $\text{Cp}^*\text{TaCl}_4$  with  $\text{PhCH=CHCH}_2\text{MgCl}$ .  $\text{Cp}^*\text{Ta}(\eta^3\text{-allyl})_2$  was only characterized by  $^1\text{H}$  NMR and MS. In the formation of  $\text{Cp}^*\text{Ta}(\eta^3\text{-1-phenylallyl})_2$ , tantalum is reduced from Ta(V) to Ta(III), and dienes such as  $(\text{PhCH=CHCH}_2)_2$  from the coupling of the allyl ligands are observed.<sup>198</sup> The presence of an imido ligand in  $\text{Cp}^*\text{Ta}^{\text{V}}(\text{=NR})\text{Cl}_2$  prevents the reduction of the metal in its reaction with  $(\text{allyl})\text{MgBr}$ , yielding the fluxional bis(allyl) complex  $\text{Cp}^*\text{Ta}^{\text{V}}(\text{=NR})(\eta^1\text{-C}_3\text{H}_5)(\eta^3\text{-C}_3\text{H}_5)$  ( $\text{R} = \text{Bu}^t, 2,6\text{-Pr}_2\text{-C}_6\text{H}_3$ ).<sup>199</sup>

Nb(III) allyl and 1-azaallyl complexes  $\text{Cp}'_2\text{Nb}(\eta^3\text{-CH}_2\text{CRCH}_2)$  ( $\text{R} = \text{H}, \text{Me}, \mathbf{73a}$ ),  $\text{Cp}'_2\text{Nb}(\eta^3\text{-CHR}'\text{CHCHR}'')$  ( $\text{R}' = \text{R}'' = \text{SiMe}_2\text{Bu}^t; \text{R}' = \text{H}, \text{R}'' = \text{SiPh}_3, \mathbf{73b}$ ) and  $\text{Cp}'_2\text{Nb}[\text{N}(\text{SiMe}_3)\text{C}(\text{Bu}^t)\text{-CH}_2]$  ( $\mathbf{73c}$ ) have been prepared from reactions of  $(\text{Cp}'_2\text{NbCl})_2$  with the corresponding allyl

Grignard (for  $\mathbf{73a}$ ), allyl potassium (for  $\mathbf{73b}$ ), and Li(1-azaallyl) reagents.<sup>140,200</sup> ( $\mathbf{73a}$ ) reacts with  $\text{O}_2$  giving  $\eta^1$ -allyl oxo complexes  $\text{Cp}'_2\text{Nb}(\text{=O})(\eta^1\text{-CH}_2\text{CRCH}_2)$ .

Thermolysis of  $(\eta^5\text{-C}_5\text{H}_4\text{CMe}_2\text{R})\text{Nb}(\text{NMe}_2)_2(\text{=NAr})$  ( $\text{R} = \text{CH}_2\text{CH=CH}_2, \text{Ph}, \text{CH}_2\text{Ph}; \text{Ar} = 2,6\text{-Pr}_2\text{-C}_6\text{H}_3$ ) leads to interesting intramolecular C–H activation with elimination of  $\text{HNMe}_2$  to give *ansa*-type half-sandwich (see *Half-sandwich Complexes*) niobiocenes ( $\mathbf{74a-c}$ ).<sup>201</sup>

(74a)

(74b)

(74c)  $\text{Ar} = 2,6\text{-Pr}_2\text{-C}_6\text{H}_3$ 

In addition to ( $\mathbf{73c}$ ), other heteronuclei  $\eta^3$  complexes have also been reported. Protonation of  $\text{M}(\text{NMe}_2)_5$  with trialkylguanidines  $(\text{RNH})_2\text{C=NR}$  produces dianionic guanidinate complexes  $\text{M}(\text{NMe}_2)_3[\eta^3\text{-N,C,N-(RN)}_2\text{C=NR}]$  ( $\text{R} = \text{Pr}^i, \mathbf{75}, \text{Cy}$ ).<sup>202</sup> Reaction of ( $\mathbf{75}$ ) with  $\text{Me}_3\text{SiCl}$  yields monoanionic guanidinate complex  $\text{Ta}(\text{NMe}_2)_3\text{Cl}[(\text{Pr}^i\text{N})_2\text{-CN}(\text{SiMe}_3)\text{Pr}^i]$ .<sup>203</sup> Carbodiimide insertion into M–amide bonds occurs in the reactions of  $\text{M}(\text{NMe}_2)_5$  with  $\text{RN=C=NR}$  ( $\text{R} = \text{Cy}, \text{Pr}^i$ ), yielding monoanionic guanidinate  $[\eta^3\text{-N,C,N-(RN)}_2\text{C(NMe}_2)]\text{M}(\text{NMe}_2)_4$ .<sup>204</sup> Benzamidinate complexes  $[\text{PhC}(\text{NSiMe}_3)_2]_2\text{TaMe}_3$ <sup>24</sup> and  $\text{Nb}(\text{=ER})\text{-[ArC(NSiMe}_3)_2]_2\text{Cl}$  ( $\text{ER} = \text{O}, \text{NBu}^t; \text{Ar} = \text{Ph}, 4\text{-Me-C}_6\text{H}_4$ )<sup>205</sup> have been prepared from the reactions of  $\text{Li[ArC(NSiMe}_3)_2]$  with  $\text{TaMe}_3\text{Cl}_2$  and  $\text{Nb}(\text{=ER})\text{Cl}_3(\text{py})_2$ , respectively. The reaction of  $\text{Nb}(\text{=NBu}^t)\text{Cl}_3(\text{py})_2$  with  $\text{Li[PhC(NSiMe}_3)_2]$  yields  $\text{Nb}(\text{=NBu}^t)[\text{PhC(NSiMe}_3)_2]\text{-Cl}_2(\text{py})$ .

Cyclooctatetraene (COT) binds to the early d-block metals in a variety of coordination modes.  $\eta^8\text{-}, \eta^4\text{-}, \eta^3\text{-}$  and  $\eta^2\text{-}$  COT ligands have been reported. These include a series of  $\eta^3\text{-COT}$  Ta complexes such as  $(\eta^5\text{-R}^i\text{Cp})\text{Ta}(\eta^4\text{-diene})(\eta^3\text{-COT})$  (diene = butadiene, isoprene, 2,3-dimethylbutadiene;  $\text{R}^i\text{Cp} = \text{Cp}^*, \text{C}_5\text{H}_4\text{Me}, \text{Cp}$ ). They are prepared from the reactions of  $(\eta^5\text{-R}^i\text{Cp})\text{TaCl}_2(\eta^4\text{-diene})$  with  $(\text{COT})\text{Li}_2$ . The addition of  $\text{B}(\text{C}_6\text{F}_5)_3$  to  $\text{Cp}^*\text{Ta}(\eta^4\text{-C}_4\text{H}_6)(\eta^3\text{-COT})$  affords  $\text{Cp}^*\text{Ta}(\eta^4\text{-C}_4\text{H}_6)[\text{C}_8\text{H}_8\text{B}(\text{C}_6\text{F}_5)_3]$  containing a substituted bicyclo[5.1.0]octadienyl ligand.<sup>206</sup>

### 7.2 $\eta^4$ -Complexes

Chemistry of Nb and Ta complexes with  $\eta^4$ -ligands has grown considerably. Among the  $\eta^4$  complexes, those with  $\eta^4$ -butadiene ( $\eta^4\text{-C}_4\text{H}_6$ ) are the best characterized, and they are the subject of a review by Nakamura and Mashima.<sup>207</sup> This paper focuses on complexes with other  $\eta^4$ -ligands such as  $\eta^4$ -arene,  $\eta^4$ -cyclooctadiene, and  $\eta^4$ -diazabutadiene.

$\eta^4$ -Butadiene complex  $\text{CpTaCl}_2(\eta^4\text{-C}_4\text{H}_6)$ , prepared from the reaction of  $\text{CpTaCl}_4$  with  $(\text{C}_4\text{H}_6)\text{Mg}$ , is treated with  $\text{NaCp}$  to yield the  $\eta^2$ -butadiene complex  $\text{Cp}_2\text{Ta}(\eta^1\text{-Cp})(\eta^2\text{-C}_4\text{H}_6)$  (**76**). Treatment of (**76**) and  $\text{CpCp}^*\text{TaCl}(\eta^2\text{-C}_4\text{H}_6)$  with  $(\text{Cp}_2\text{ZrMe})^+[\text{MeB}(\text{C}_6\text{F}_5)_3]^-$  results in formation of  $\text{Cp}_2\text{Ta}(\eta^4\text{-C}_4\text{H}_6)^+$  (**77a**) and  $\text{CpCp}^*\text{Ta}(\eta^4\text{-C}_4\text{H}_6)^+$  (**77b**). In reactions of (**77a**) with ketones and nitriles, and (**77b**) with ketones, insertion of ketones and nitriles into the butadiene ligands is observed, giving cationic seven-membered metallacyclic  $\sigma$ -allyl complexes.<sup>191,208</sup> Similar reactions of (**77a**) with alkynes give metallacyclic ( $\pi$ -allyl)metallocene cations.<sup>208</sup>

When the dialkylated complexes  $\text{Cp}^*\text{NbR}'_2(\text{RCCR})$  ( $\text{R} = \text{SiMe}_3$ ,  $\text{R}' = \text{Me}$ ,  $\text{CH}_2\text{SiMe}_3$ ,  $\text{Np}$ ) are treated with 1 equiv of isocyanide  $\text{XylNC}$  under heat, hydrogen migration occurs, giving diene complexes  $\text{Cp}^*\text{Nb}(=\text{NXyl})(\eta^4\text{-CHRCRCR}'\text{CHR}'')$  ( $\text{R}' = \text{Me}$ ,  $\text{R}'' = \text{H}$ ;  $\text{R}' = \text{CH}_2\text{R}$ ,  $\text{R}'' = \text{R}$ ) and the niobacyclohept-2-ene  $\text{Cp}^*\text{Nb}(=\text{NXyl})(\eta^2\text{-CH}_2\text{CMe}_2\text{-CH}_2\text{CH}(\text{Np})\text{CR}=\text{CR})$ .<sup>209</sup>

In the  $\text{Na}/\text{Hg}$  reduction of aryloxides  $\text{Nb}(\text{OAr})_3\text{Cl}_2$  ( $\text{Ar} = 2,6\text{-Ph}_2\text{-C}_6\text{H}_2\text{R}$ ,  $\text{R} = \text{H}$ ,  $\text{Ph}$ ) under  $\text{H}_2$ , 1,2-hydrogenation of an *ortho*-phenyl substituent occurs, leading to a cyclohexadiene group in  $\text{Nb}(\text{OC}_6\text{H}_2\text{RPh-}\eta^4\text{-C}_6\text{H}_7)(\text{OAr})_2$ .<sup>210</sup> In the presence of 1,3-cyclohexadiene ( $\text{C}_6\text{H}_8$ ), the  $\text{Na}/\text{Hg}$  reduction of  $\text{M}(\text{OAr}')_n\text{Cl}_{5-n}$  ( $n = 2, 3$ ,  $\text{Ar}' = 2,6\text{-Pr}_2\text{-C}_6\text{H}_3$ ) leads to formation of cyclohexadiene adducts  $\text{M}(\text{OAr}')_n\text{Cl}_{3-n}(\eta^4\text{-C}_6\text{H}_8)$ , respectively. The cyclohexadiene ligand binds strongly in the complexes, and does not readily undergo displacement with added reagents such as  $\text{PMe}_2\text{Ph}$ . One of the adducts,  $\text{Ta}(\text{OAr}')_3(\eta^4\text{-C}_6\text{H}_8)$ , catalyzes the disproportionation of 1,3-cyclohexadiene into cyclohexene and benzene as well as the hydrogenation of 1,3-cyclohexadiene and cyclohexene into cyclohexane. Addition of 1,3-cyclohexadiene to  $\text{Ta}(\text{OAr}'')_2(\text{H})_3(\text{PMe}_2\text{Ph})_2$  ( $\text{Ar}'' = 2,6\text{-Cy}_2\text{-C}_6\text{H}_3$ ,  $2,6\text{-Cy}_2\text{-3,5-Ph}_2\text{-C}_6\text{H}_3$ ) leads to  $\text{Ta}(\text{OAr}'')_2(\eta^1\text{-C}_6\text{H}_{10}\text{-}\eta^4\text{-C}_6\text{H}_7)$  (**78**) containing a partially hydrogenated non-Diels–Alder dimer of 1,3-cyclohexadiene.<sup>211</sup>

The first tris(arene)niobium complex,  $[\text{Nb}(1\text{-}4\text{-}\eta^4\text{-anthracene})_3]^-$ , prepared by the  $\text{Na}$  or  $\text{K}$  anthracene reduction of  $\text{NbCl}_4(\text{THF})_2$ , undergoes facile anthracene displacement in the presence of  $\text{CO}$  to afford  $[\text{K}(18\text{-crown-6})(\text{THF})_2][\text{Nb}(\text{CO})_6]$ .<sup>212</sup> Reduction of  $\text{TaCl}_5$  by sodium naphthalene provides  $[\text{Na}(\text{THF})][\text{Ta}(\eta^4\text{-naphthalene})_3]$ , the first homoleptic naphthalene complex of a third row transition metal. This complex reacts with  $\text{CO}$  and anthracene to give  $[\text{Ta}(\text{CO})_6]^-$  and  $[\text{Ta}(1\text{-}4\text{-}\eta^4\text{-anthracene})_3]^-$ , respectively. The latter product reacts with cyclooctatetraene (COT) to give  $[\text{Ta}(\text{COT})_3]^-$ .<sup>213</sup>

Half-sandwich (*see Half-sandwich Complexes*) complexes  $\text{Cp}^*\text{Nb}\{\eta^4\text{-}o\text{-(CH}_2)_2\text{C}_6\text{H}_4\text{Cl}_2\}$  and  $\text{Cp}^*\text{Ta}(\eta^4\text{-C}_{14}\text{H}_{10})\text{Cl}_2$  with an extended conjugated  $\eta^4$ -diene ligand such as *o*-xylylene and anthracene have been prepared from the reactions of  $\text{Cp}^*\text{MCl}_4$  with *o*- $\text{C}_6\text{H}_4(\text{CH}_2\text{MgCl})_2$  and  $\text{Mg}(\text{anthracene})(\text{THF})_3$ , respectively.<sup>214</sup>

The germole reagent  $\text{C}_4\text{Me}_4\text{Ge}(\text{Me})\text{SiMe}_3$  reacts with  $\text{TaCl}_5$  to give  $[(\eta^4\text{-C}_4\text{Me}_4\text{GeMeCl})\text{TaCl}_3(\text{Et}_2\text{O})_x]_2$  ( $x = 0.5\text{--}1.0$ ), which reacts with  $\text{CpTiI}$  to give air-stable  $\text{Cp}(\eta^4\text{-C}_4\text{Me}_4\text{GeMeCl})\text{TaCl}_2$  (**79**).<sup>215</sup>

$\text{Cp}^*\text{Ta}(\text{R}_2\text{-dad})\text{Cl}_2$  ( $\text{R}_2\text{-dad} = \text{RN-CH=CH-NR}^{2-}$ ;  $\text{R} = \text{Pr}^i$ ,  $\text{Bu}^t$ , **80**) are prepared from the reactions of  $\text{Cp}^*\text{TaCl}_4$  with  $\text{Li}_2(\text{R}_2\text{-dad})$ . The *N,N'*-disubstituted diazabutadiene ( $\text{R}_2\text{-dad}$ ) ligands in these complexes are bound to the metal center with a  $\sigma^2(\text{N},\text{N}')$ ,  $\pi(\text{C},\text{C}')$ -coordination mode.<sup>216</sup> The Nb ene-diamido ene-diolato complexes  $\text{Cp}^*\text{NbCl}_2(\text{Me},\text{Phdad})$  and  $\text{Cp}^*\text{NbCl}_2[\text{O}(\text{R})\text{C}=\text{C}(\text{R})\text{O}]$  are prepared from the reactions of  $\text{Cp}^*\text{NbCl}_2(\text{Me}_3\text{SiCCSiMe}_3)$  with  $\text{Me},\text{Phdad}$  ( $\text{PhN}=\text{CMe}=\text{CMe}=\text{NPh}$ ) and diketones  $\text{R-CO-CO-R}$  ( $\text{R} = \text{Me}$ ,  $\text{Ph}$ ).<sup>217</sup> Similarly,  $\text{Cp}^*\text{TaCl}_4$  reacts with *o*- $\text{C}_6\text{H}_4(\text{NLSiPr}^i)_2$  giving (**81**), where the diamide ligand is coordinated in an  $\eta^4$ -fashion via donation of electron density from the phenylene ring to the metal.<sup>218</sup>

A neutral group 5 bent metallocene analog (**82**) containing the unusual  $\eta^4$ -TBM dianion (TBM = tribenzylidene-methane) has been prepared from the reaction of  $(\text{TBM})\text{TaMe}_2\text{Cl}$  and  $\text{LiCp}$ .<sup>219</sup> Both  $\text{TBM}^{2-}$  and  $\text{Cp}^-$  ligands are formally six-electron donors but differ in their respective charges. Compounds such as (**82**) are of interest as neutral group 4 counterparts of cationic metallocene alkyls that important homogeneous Ziegler–Natta polymerization catalysts (*see Ziegler–Natta Catalysts*).

### 7.3 $\eta^5$ -Complexes

Many Nb and Ta complexes containing cyclopentadienyl ligands have been described in other sections. 3-D

metallasiloxanes, prepared from reactions of  $\text{Cp}^*\text{TaMe}_4$  with organosilanetriols  $\text{RSi}(\text{OH})_3$ , as models for catalytically useful transition metals supported on silica was recently reviewed.<sup>220</sup> In this section, the  $\eta^5$ -ligands obtained from the reduction of arene rings will be described.

$\text{M}(\eta^5\text{-9-Ph-C}_{13}\text{H}_8)(\text{CO})_4$  ( $\eta^5\text{-9-Ph-C}_{13}\text{H}_8$  = phenylfluorenyl) have been prepared from  $[\text{M}_2(\mu\text{-Cl})_3(\text{CO})_8]^-$  and  $\text{Li}(\eta^5\text{-phenylfluorenyl})$ .<sup>221</sup>

Hydrogenolysis of  $^R[\text{P}_2\text{N}_2]\text{NbCH}_2\text{SiMe}_3$  ( $R = \text{Cy}, \text{Ph}$ ) in benzene and toluene causes hydride addition to the aromatic solvent, resulting in the formation of  $^R[\text{P}_2\text{N}_2]\text{Nb}(\eta^5\text{-cyclohexadienyl})$  and  $^R[\text{P}_2\text{N}_2]\text{Nb}(\eta^5\text{-methylcyclohexadienyl})$ , respectively.<sup>222</sup> One-electron reduction of the P-Ph group in  $^{\text{Ph}}[\text{P}_2\text{N}_2]\text{NbCl}$  yields (**83**) containing a cyclohexadienyl moiety formed via a C-C bond formation between the ipso carbons of the two Ph groups.<sup>223</sup>  $(\text{ArN}=\text{})(\text{ArNH})\text{TaMe}(\text{OTf})$  ( $\text{Ar} = 2,6\text{-dimesitylphenyl}$ , **84a**) reacts with  $\text{H}_2$  to convert one mesityl group into a  $\eta^5$ -cyclohexadienyl ligand, forming  $(\text{ArN}=\text{})[2-(\eta^5\text{-2,4,6-Me}_3\text{-C}_6\text{H}_3)\text{-6-mesitylC}_6\text{H}_3\text{NH}]\text{Ta}(\text{OTf})$  (**84b**).<sup>224,225</sup> D-labeling studies indicate that reaction proceeds through a hydride intermediate  $(\text{ArN}=\text{})(\text{ArNH})\text{TaH}(\text{OTf})$  (**84c**), and a reversible intramolecular hydride transfer between Ta and the aromatic ring.

Reactions of 17-e  $\text{Nb}^{\text{II}}(2,4\text{-C}_7\text{H}_{11})_2(\text{L})$  species ( $\text{C}_7\text{H}_{11}^-$  = dimethylpentadienyl;  $\text{L} = \text{PEt}_3, \text{PMe}_2\text{Ph}$ ) with CO lead to spontaneous reduction of these complexes and formation of 18-e  $\text{Nb}^{\text{I}}(2,4\text{-C}_7\text{H}_{11})(\text{L})(\text{CO})_3$ . These products are also susceptible to reduction by alkali metals, presumably leading to the dianion  $\text{Nb}(2,4\text{-C}_7\text{H}_{11})(\text{CO})_3^{2-}$ , which is oxidized under CO to give  $\text{Nb}^{\text{I}}(2,4\text{-C}_7\text{H}_{11})(\text{CO})_4$ .<sup>226</sup>

#### 7.4 $\eta^6$ -Complexes

$\eta^6$ -Arene complexes are usually prepared by the following methods: (i) metal vapor synthesis (see *Metal Vapor Synthesis of Transition Metal Compounds*).<sup>227</sup> (ii)  $\text{Al}/\text{AlX}_3$  reduction of a metal halide in the presence of the arene; and (iii) alkyne cyclotrimerization (see *Cyclodimerization & -trimerization Reactions*). Synthetic procedures to obtain  $\eta^6$ -arene derivatives have been reviewed by Pampaloni and Calderazzo.<sup>228</sup> Over the past ten years, studies in this

area have been focused on the reactivities of  $\eta^6$ -arene complexes.

Reaction of  $(\text{TMEDA})_2\text{Nb}^{\text{II}}_2\text{Cl}_5\text{Li}(\text{TMEDA})$  with the amide  $\text{Ph}_2\text{NK}$  leads to the formation of several compounds including the  $\text{Nb}^{\text{III}}$  anion (**85a**) and neutral, diamagnetic  $\text{Nb}^0$  (**85b**). (**85a**) is the product of oxidative addition (see *Oxidative Addition*) of two Nb centers to the *ortho* C-H bond of a Ph group. (**85a**) then undergoes reductive elimination (see *Reductive Elimination*) to restore the C-H bond to form (**85b**).<sup>229</sup>

$[\text{Nb}(\text{Mes})_2]^+$ , produced from the 1-e oxidation of bis(mesitylene) complex  $\text{Mes}_2\text{Nb}$ , adds alkynes to give  $[\text{Nb}(\text{Mes})_2(\text{RC}\equiv\text{CR})]^+$  ( $R = \text{Me}, \text{Ph}$ ). Thermal treatment of  $[\text{Nb}(\text{Mes})_2(\text{RC}\equiv\text{CR})](\text{BAR}_4)$  gives  $(\text{RC}\equiv\text{CR})\text{Nb}(\eta^6\text{-C}_6\text{H}_4\text{X})_2\text{B}(\text{C}_6\text{H}_4\text{X})_2$  ( $R = \text{Me}, \text{X} = \text{H}, p\text{-F}$ , **86a**;  $R = \text{Ph}, \text{X} = \text{H}$ , **86b**) containing Nb bonded to two of the four aromatic rings of the tetraphenylborato ligand in a bent fashion. Alkyne displacement in (**86a**) by CO gives  $\text{Nb}(\text{CO})(\eta^6\text{-C}_6\text{H}_4\text{X})_2\text{B}(\text{C}_6\text{H}_4\text{X})_2$  ( $\text{X} = \text{H}, p\text{-F}$ ).<sup>230</sup>  $\text{Mes}_2\text{Nb}$  is oxidized by  $\text{XMn}(\text{CO})_5$  ( $\text{X} = \text{Cl}, \text{I}$ ) and  $\text{XRe}(\text{CO})_5$  ( $\text{X} = \text{Br}, \text{I}$ ) to give  $\text{Mes}_2\text{NbX}$  and  $\text{Mes}(\text{CO})_2\text{Nb}(\mu\text{-X})_2\text{Re}(\text{CO})_3$ , respectively.<sup>231</sup>

$\eta^6$ -Hexamethylbenzene alkyl and aryl Ta(III) complexes supported by aryloxy and arenethiolate ligands have been reported. These include  $(\eta^6\text{-C}_6\text{Me}_6)\text{Ta}(\text{OAr})_2\text{Me}$ ,  $(\eta^6\text{-C}_6\text{Me}_6)\text{Ta}(\text{OAr})\text{RR}'$  ( $R = R' = \text{Me}, \text{Et}, \text{CH}_2\text{SiMe}_3, \text{Ph}$ ;  $R = \text{H}, R' = \text{CH}_2\text{SiMe}_3$ ),  $(\eta^6\text{-C}_6\text{Me}_6)\text{Ta}(\text{OAr})(\text{R})\text{X}$  ( $\text{X} = \text{Cl}, R = \text{CH}_2\text{SiMe}_3, \text{Ph}$ ;  $\text{X} = \text{Br}, R = \text{Me}, \text{Et}$ ) ( $\text{Ar} = 2, 6\text{-Pr}^i_2\text{-C}_6\text{H}_3$ ).<sup>232</sup>

#### 7.5 $\eta^8$ -Complexes

$\text{Ta}(\eta^8\text{-COT}')\text{Me}_3$  (**87**) was prepared from the reaction of  $\text{TaCl}_2\text{Me}_3$  with  $\text{Li}_2(\text{COT}')$  [ $\text{COT}' = 1,4\text{-bis}(\text{trimethylsilyl})\text{cyclooctatetraene}$ ]. It reacts with  $(\text{NHPr}^i_2\text{Et})\text{Cl}$  to yield  $\eta^8$ -pentalene (**88**).<sup>233</sup>

Complexes (**89**) containing a noncyclic  $\eta^8$ -tetraene ligand are prepared from reactions of  $(\text{RC}_5\text{H}_4)\text{NbCl}_4$  with dimethylpentadienyl (dienyl) anion. The reactions initially give  $(\text{RC}_5\text{H}_4)\text{Nb}(\eta^5\text{-dienyl})(\eta^3\text{-dienyl})$ , which subsequently undergo intramolecular coupling between the two dienyl ligands, yielding (**89**).<sup>234</sup>

## 8 HETEROMETAL CLUSTERS

Heterobimetallic hydride and alkylidyne complexes are discussed in Sections 3.2.3 and 4.1, respectively. C–H activation of the alkylidyne (*see Alkylidyne*) complexes are discussed in Section 9.1 below.

The Ta–Li alkylidene (**29**) (Section 4.2) containing an anionic triazacyclononane ligand ( $Pr^i_2-tacn^-$ ) reacts with  $FeCl_2(TEMEDA)$  or  $[RhCl(COD)]_2$  to form bimetallic (**90**) and (**91**), respectively.<sup>121</sup> In both products, the two metals in close proximity and linked by single-atom bridges.

## 9 NIOBIUM AND TANTALUM COMPLEXES IN CATALYSIS AND METAL-MEDIATED ORGANIC SYNTHESIS

### 9.1 C–H Bond Activation

This section reviews C–H activation reactions that have not been discussed in earlier sections.

Silyl complexes,  $Cp_2Ta^{III}(L)SiR_3$  ( $L = PMe_3, CO$ ), activate C–H bonds of unhindered arenes such as benzene, toluene, and *m*-xylene.  $Cp_2Ta(PMe_3)(SiBu^t_2H)$  reacts in neat arenes

(ArH) to produce aryl complexes  $Cp_2Ta(PMe_3)Ar$ . Complexes with smaller silyl ligands give equilibrium mixtures of silyl and aryl complexes in which the silyl is favored. Thermodynamic studies reveal that the Ta–Si bonds in  $Cp_2Ta(PMe_3)SiR_3$  ( $R_3 = Bu^t_2H; Me_3$ ) are 5.4–7.9 kcal mol<sup>–1</sup> weaker than the Ta–Ph bond in  $Cp_2Ta(PMe_3)Ph$ , and suggest that the strength of the Ta–Si bonds are probably comparable to or greater than that of a Ta–alkyl bond.<sup>235</sup>

Bridging alkylidyne (*see Alkylidyne*) complexes (**28a–b**) (Section 4.1) react with TMEDA, leading to C–H activation of the methyl group in  $-NMe_2$  and the elimination of  $ZnCl_2$ , giving the alkylidene (**92a–b**).<sup>41,119</sup>

Silica-supported Ta hydride ( $(\equiv SiO)_2Ta-H$  (**93a**) presents unusual properties in the activation of alkanes. It catalyzes the metathesis reaction of alkanes to give higher and lower molecular weight alkanes, and the hydrogenolysis of alkanes such as ethane to methane.<sup>236</sup> This hydride also activates the C–H bonds of cycloalkanes to form the corresponding surface metal-cycloalkyl complexes, and catalyses the H/D exchange reaction between  $CH_4$  and  $CD_4$ , producing the statistical distribution of methane isotopomers.<sup>237</sup>

C–H activation using the aryloxy supported Ta complexes has been discussed in Section 6.3.<sup>53,238,239</sup> Additional examples include the thermal conversion of the hydride  $Ta(O-2,6-Ph_2-C_6H_3)_2(H)_2Cl(PMe_3)_2$  into the monocyclometalated complex (**94**).<sup>60</sup> Reaction of  $Cp^*TaCl_4$  with (cb)K (>3 equiv) leads to the species  $(C_5Me_4CH_2)Ta(cb)_2Cl$ , in which one of the ring methyl C–H bonds of the  $Cp^*$  ligand has been cleaved.<sup>240</sup>

Ta amide (**14**) and *ansa*-type half-sandwich (see *Half-sandwich Complexes*) niobiocenes (**74a–c**) from intramolecular C–H activation with elimination of HNMe<sub>2</sub> are discussed in Sections 7.1 and 3.1.1. The –NMe<sub>2</sub> group in (**95**) undergoes  $\beta$ -H abstraction by a benzyl ligand to give (**96**).<sup>40</sup> Alkylidyne-mediated C–H activation in the –NMe<sub>2</sub> group is observed in the formation of alkylidenes (**92a–b**) (Section 8).<sup>41</sup>

## 9.2 Alkene Polymerization

The use of Nb and Ta cyclopentadienyl complexes as catalysts for olefin polymerization has been actively studied (see *Oligomerization & Polymerization by Homogeneous Catalysis*). These complexes include ( $\eta^5\text{-C}_5\text{R}_5$ )( $\eta^4$ -diene)TaMe<sub>2</sub> (R = H, Me),<sup>241</sup> ( $\eta^5\text{-C}_5\text{R}_5$ )(TBM)TaMe<sub>2</sub> and (fluorenyl)(TBM)TaMe<sub>2</sub> (TBM = tribenzylidenemethane),<sup>242</sup> borollide Cp\*[ $\eta^5\text{-C}_4\text{H}_4\text{BN}(\text{CHMe}_2)_2$ ]TaCl<sub>2</sub>,<sup>243</sup> and Cp\*Ta(=NAr)( $\eta^1\text{-C}_3\text{H}_5$ )( $\eta^3\text{-C}_3\text{H}_5$ ) (Ar = 2,6-Pr<sup>i</sup><sub>2</sub>-C<sub>6</sub>H<sub>3</sub>).<sup>199</sup> They are typically activated with methylaluminoxane (MAO),<sup>241–243</sup> (Ph<sub>3</sub>C)<sup>+</sup>–[B(C<sub>6</sub>F<sub>5</sub>)<sub>4</sub>]<sup>–</sup>, or B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>.<sup>199</sup>

The catalytic activities of Nb and Ta complexes Cp\*M( $\eta^4$ -diene)Cl<sub>2</sub> (M = Nb, Ta; diene = 1,3-butadiene, isoprene, 2,3-dimethyl-1,3-butadiene) activated by MAO have been compared. They both give polyethylene with very narrow polydispersities at low temperature ( $M_w/M_n$  as low as 1.05). The Nb complexes are superior to the Ta complexes in terms of the catalyst activity and the polydispersity.<sup>244,245</sup> Cp\*Ta(*o*-xylylene)Cl<sub>2</sub>/MAO is twice as catalytically active and the molecular weight distribution of the polyethylene is much narrower than that using Cp\*M( $\eta^4$ -1,3-butadiene)Cl<sub>2</sub>/MAO as catalysts.<sup>246</sup>

Substituted hydridotris(pyrazolyl)borato (Tp') complexes Tp'NbMe<sub>2</sub>(PhC≡CMe), when treated with B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>, polymerize ethylene. It is interesting to note that bulky (Tp<sup>Me2,4-Cl</sup>)NbMe<sub>2</sub>(PhC≡CMe) yields a catalyst that is far more active than TpNbMe<sub>2</sub>(PhC≡CMe).<sup>247</sup>

Insertion of H<sub>2</sub>C=CHX (X = OR; R = Me, Et, Pr<sup>n</sup>, Pr<sup>i</sup>, CH=CH<sub>2</sub>, Ph) into (Bu<sup>t</sup><sub>3</sub>SiO)<sub>3</sub>TaH<sub>2</sub> affords (Bu<sup>t</sup><sub>3</sub>SiO)<sub>3</sub>(H)-TaCH<sub>2</sub>CH<sub>2</sub>X, which  $\beta$ -X-eliminates to give ethylene and (Bu<sup>t</sup><sub>3</sub>SiO)<sub>3</sub>HTaX. These reactions and their relevance to incorporation of functionalized monomers in Ziegler–Natta

(see *Ziegler–Natta Catalysts*) copolymerizations have been studied.  $\beta$ -X-elimination rates are found to be inversely proportional to the size of R.<sup>248</sup>

## 9.3 Alkene Dimerization

Reduction of TaCl<sub>5</sub> with Zn in the presence of alkyne RC≡CR and solvents (L) is believed to yield Ta chloro alkyne complexes, which react with lithium alkoxides tethered to alkenyl groups to give chemo- and stereoselective addition of terminal alkenyl groups.<sup>249</sup> Alkoxy-directed insertion of C=C bonds into Ta-alkyne complexes plays a critical role through the following mechanism.

Reactions of TaCl<sub>5</sub> with alkylating agents such as MeLi are believed to give in situ TaCl<sub>3</sub>Me<sub>2</sub>, which catalyzes selective trimerization of ethene to 1-hexene.<sup>250</sup> Theoretical studies of the detailed mechanism of the olefin trimerization provide insights why this catalyst selectively trimerizes rather than dimerizes or polymerizes ethene.

The theoretical studies confirm intermediacy of tantalacycloheptane in the trimerization process. The conversion of tantalacycloheptane to the Ta-(1-hexene) complex follows. The dimerization is disfavored by the nonexistence of such concerted reductive elimination process for the tantalacyclopentane. The bimolecular process of tetramerization and possible higher oligomerization cannot compete with the facile reductive elimination (see *Reductive Elimination*).<sup>251</sup>

The silica-supported Ta hydride (≡SiO)<sub>2</sub>Ta–H (**93a**) reacts with PMe<sub>3</sub> to give (≡SiO)<sub>2</sub>Ta(H)(PMe<sub>3</sub>) (**93b**). In comparison to (**93a**), the phosphine hydride (**93b**) is inactive toward metathesis of acyclic alkanes, but affords the oligomerization of ethylene into 1-butene and higher oligomers.<sup>252</sup>

## 9.4 Metathesis of Alkanes and Alkenes and Metathesis Polymerization

C–C and C–H bond activation of alkanes by silica-supported group 4 and 5 hydrides is the subject of a

recent review by Lefebvre and Basset.<sup>253</sup> Alkane metathesis catalyzed by  $(\equiv\text{SiO})_2\text{Ta}-\text{H}$  (**93a**) is discussed briefly in Section 9.1. Over (**93a**), ethane is transformed into an equimolar mixture of propane and methane.<sup>236</sup>  $^{13}\text{C}$ -monolabeled ethane is converted, in addition to higher alkanes, to its unlabeled and dilabeled isotopomers.<sup>254</sup> The relative reactivity of  $\text{Ta}^{\text{III}}$  (**93a**) and  $\text{Ta}^{\text{V}}$   $(\equiv\text{SiO})_x\text{Ta}(\text{=CHCMe}_3)(\text{CH}_2\text{CMe}_3)_{3-x}$  ( $x = 1, 2$ , **97**) toward alkanes has been studied. The reaction of C–C bonds with a surface Ta complex containing both neopentyl and neopentylidene groups gives cross-metathesis products with the  $\text{Bu}^t$  markers. The studies using (**97**) as catalysts provide the first evidence for alkane cross-metathesis.<sup>255</sup>

As discussed in Sections 4.2 and 6.1, alkylidenes (**30a–b**) and tantalacyclobutane (**31a**) initiate ring-opening metathesis polymerization with strained cyclic olefins.<sup>123</sup> *cis*-Dialkyl Ta complexes  $\text{Cp}^*\text{TaR}_2(\eta^4\text{-butadiene})$  [ $\text{R}_2 = (\text{CH}_2\text{Ph})_2$ ,  $(\text{CH}_2\text{SiMe}_3)_2$ ,  $\text{Me}(\text{Np})$ ] are catalyst precursors for ring-opening metathesis polymerization (ROMP) of norbornene to poly(norbornene) with a high *cis*-vinylene double-bond (97–99%) content. The *o*-xylylene analog  $\text{Cp}^*\text{Ta}(\text{CH}_2\text{Ph})_2[\eta^4\text{-}o\text{-(CH}_2)_2\text{C}_6\text{H}_4]$  is also an initiator to give poly(norbornene) with a high *trans*-vinylene double-bond (92–95%) content. These results indicate the control of stereoselectivity in the ROMP of norbornene by butadiene and *o*-xylylene ligands, as a result of the congestion between  $\text{Cp}^*$  and these auxiliary ligands.<sup>256</sup>

$\text{NbCl}_3(\text{DME})$  and *mer*-( $\text{DME})\text{Cl}_3\text{Nb}=\text{NPh}$  serve as effective catalysts or precatalysts in imine metathesis of aldimines  $\text{RCH}=\text{NR}'$  and  $\text{R}''\text{CH}=\text{NR}^x$  to give  $\text{RCH}=\text{NR}^x$  and  $\text{R}''\text{CH}=\text{NR}'$ .<sup>257</sup>

## 9.5 Hydrodenitrogenation and Hydrodeoxygenation

Catalytic hydrodenitrogenation (HDN) and hydrodeoxygenation (HDO) are the processes of removing nitrogen and oxygen, respectively, from petroleum feedstocks to provide more processable and environmentally compatible liquid fuels. A review of heterogeneous HDN process and homogeneous models summarized the research till ca. 1997.<sup>258</sup>

$\beta\text{-H}$  abstraction of amide ligands to give  $\eta^2\text{-}N,C$ -heterocyclic complexes is discussed in Section 5.7. Thermolysis of  $\text{Ta}(\text{NC}_9\text{H}_{10})(\text{O}-2,6\text{-Pr}^i_2\text{-C}_6\text{H}_3)\text{R}_2\text{Cl}$  ( $\text{NC}_9\text{H}_{10}^- = \text{tetrahydroquinolinyl}$ ;  $\text{R} = \text{Me, Et}$ ), which are reactivity models for fundamental HDN reactions of pyridines, however, shows no evidence for the formation of  $\eta^2\text{-}N,C$ -heterocycles arising from metallation of a tetrahydroquinolinyl ligand.<sup>259</sup>

Treatment of  $(\text{silox})_3\text{Ta}$  with arylamines  $\text{H}_2\text{NC}_6\text{H}_4\text{X}$  leads to the oxidative addition of N–H bonds to give  $(\text{silox})_3\text{-Ta}(\text{H})[\text{NH}(\text{C}_6\text{H}_4\text{X})]$  and/or C–N activation to yield  $(\text{silox})_3\text{-Ta}(\text{NH}_2)(\text{C}_6\text{H}_4\text{X})$  ( $\text{X} = 4\text{-NMe}_2$ , 4-OMe, 4-Me, 4-F, 3-F, 3-CF<sub>3</sub>, 3,5-CF<sub>3</sub>, 4-CF<sub>3</sub>, 4-Ph).  $(\text{silox})_3\text{Ta}$  activates the C–O bonds in 1,2-dihydrofuran and 3,3-dimethyloxetane, forming the cyclic complexes (**98a–b**).<sup>260</sup> These reactions mimic key steps in HDN and HDO processes.

Structural models for the substrate-catalyst adduct in HDN catalysis have been prepared and compared with respect to O versus S-ancillary ligands.  $\eta^2\text{-}N,C$ -1,3,5-tributylpyridine complexes  $(\eta^2\text{-}N,C\text{-NC}_5\text{Bu}^t_3\text{H}_2)\text{Ta}(\text{OAr})_2\text{X}$  ( $\text{X} = \text{OBU}^t$ ,  $\text{SBU}^t$ , Br) show a severe interruption of aromaticity within the pyridine heterocycle, different rotational preferences of the  $\text{NC}_5$  plane with respect to the  $\text{Ta}(\text{OAr})_2\text{X}$  moiety, and structural differences in the aryloxy ligand. The comparison here support the ancillary ligand  $\pi$ -donor ability decreasing as  $\text{OBU}^t > \text{OAr} > \text{SBU}^t > \text{Cl} \sim \text{Br} > \text{Et}$ .<sup>261</sup>

## 9.6 Epoxidation of Olefins

Silica-supported chiral tantalum alkoxides and  $\text{Ta}(\text{=CHCMe}_3)(\text{CH}_2\text{CMe}_3)_3$  are, in the presence of (+)-tartrate, active catalysts for the asymmetric epoxidation of 2-propenol and *trans*-hex-2-en-1-ol by  $\text{Bu}^t\text{OOH}$ .<sup>262,263</sup> The enantioselective (*see Enantioselectivity*) catalytic epoxidation of unfunctionalized alkyl and aryl olefins by  $\text{H}_2\text{O}_2$  was conducted using niobocene peroxide complex  $(R, R)\text{-(+)-Cp}''_2\text{Nb}(\text{O}_2)\text{Cl}$  containing the  $\text{C}_2$ -symmetrical binaphthylcyclopentadienyl ligand ( $\text{Cp}''$ ).<sup>264</sup> Enantiomeric excesses and activities range between 2–20% and 10–55 turnovers are observed in these epoxidation reactions.

## 9.7 Hydrogenation of Alkenes and Arenes

As discussed in Section 7.3,  $(\text{ArN=})(\text{ArNH})\text{TaMe}(\text{OTf})$  ( $\text{Ar} = 2,6\text{-dimesitylphenyl}$ , **84a**) reacts cleanly with  $\text{H}_2$  to convert one mesityl group to a  $\eta^5\text{-cyclohexadienyl}$  complex (**84b**) (Section 7.3). (**84b**) is in equilibrium with the hydride  $(\text{Ar}^*\text{N=})(\text{Ar}^*\text{NH})\text{TaH}(\text{OTf})$  (**84c**). (**84b–c**) catalyze olefin hydrogenation, diene cyclization, and silane deuteration.<sup>225</sup> As discussed in Section 7.3 as well, hydrogenolysis of  $^R[\text{P}_2\text{N}_2]\text{NbCH}_2\text{SiMe}_3$  ( $\text{R} = \text{Cy, Ph}$ ) in, for example, benzene gives  $^R[\text{P}_2\text{N}_2]\text{Nb}(\eta^5\text{-cyclohexadienyl})$ . At a higher  $\text{H}_2$  pressure, this hydrogenolysis causes the catalytic hydrogenation of benzene to cyclohexane and toluene to methylcyclohexane.<sup>222</sup>

Treatment of a mixture of  $\text{Nb}(\text{O-Ar})_2(\text{CH}_2\text{SiMe}_3)_2$ ,  $\text{Nb}(\text{O-Ar})_2(\text{CH}_2\text{SiMe}_3)(\text{=CHSiMe}_3)$  ( $\text{Ar} = 2,3,5,6\text{-Ph}_4\text{-C}_6\text{H}$ ), and  $\text{PMe}_3$  under 1200 psi of  $\text{H}_2$  leads to hydrogenolysis

of Nb alkyl/alkylidene bonds but also the intramolecular hydrogenation of the *ortho*-phenyl rings of the aryloxide ligands to give Nb(O-2,6-Cy<sub>2</sub>-3,5-Ph<sub>2</sub>-C<sub>6</sub>H<sub>2</sub>)(H)<sub>2</sub>(PMe<sub>3</sub>)<sub>2</sub>.<sup>265</sup> Similar reactions are discussed in Section 7.2. These hydride derivatives containing bulky ancillary aryloxide ligands are catalysts for high regio- (*see Regioselectivity*) and stereoselective (*see Stereoselectivity*), all-*cis* hydrogenation of benzenes and polynuclear aromatic hydrocarbons. The Nb complexes also rapidly hydrogenate arylphosphine ligands such as PPh<sub>3</sub> to PPh<sub>2</sub>Cy, PPhCy<sub>2</sub> and PCy<sub>3</sub> as a new procedure for the synthesis of cyclohexylphosphines.<sup>59</sup> As discussed in Section 7.2, Ta(OAr')<sub>3</sub>(η<sup>4</sup>-C<sub>6</sub>H<sub>8</sub>) catalyzes the hydrogenation of 1,3-cyclohexadiene and cyclohexene into cyclohexane.<sup>211</sup>

i, Nb(O-2,3,5,6-Ph<sub>4</sub>-C<sub>6</sub>H)<sub>2</sub>Cl<sub>3</sub> / 3Bu<sup>n</sup>Li

ii, Ta(O-2,6-Pr<sup>i</sup>-C<sub>6</sub>H<sub>3</sub>)<sub>2</sub>(H)<sub>3</sub>(PMePh<sub>2</sub>)

The bridging alkylidyne compounds (Me<sub>3</sub>SiCH<sub>2</sub>)<sub>4</sub>M<sub>2</sub>(μ-CSiMe<sub>3</sub>)<sub>2</sub> supported on silica catalyze the exhaustive hydrogenation of a variety of aromatic substrates. Hydrogenation of benzene at 1200–1400 psi of H<sub>2</sub>, for example, gave 100% cyclohexane.<sup>266</sup>

## 9.8 Metal-mediated Hydroboration of Olefins

Olefin complexes Cp\*<sub>2</sub>M(CH<sub>2</sub>=CHR)(H) (R = H, Me) react with catecholborane (HBCat) and HBO<sub>2</sub>C<sub>6</sub>H<sub>3</sub>-4-Bu<sup>t</sup> (HBCat') to give Cp\*<sub>2</sub>M(H<sub>2</sub>BCat) and Cp\*<sub>2</sub>M(H<sub>2</sub>BCat') and the anti-Markovnikov hydroboration (*see Hydroboration*) products CatBCH<sub>2</sub>CH<sub>2</sub>R and Cat'BCH<sub>2</sub>CH<sub>2</sub>R, respectively. D-labeling studies suggest a mechanism through which HBCat reacts with the alkyl intermediates Cp\*<sub>2</sub>MCH<sub>2</sub>CH<sub>2</sub>R, via σ-bond metathesis (*see σ-Bond Metathesis*) or oxidative-addition (*see Oxidative Addition*) and reductive elimination (*see Reductive Elimination*) sequences, to generate the alkylboranes and the hydride Cp\*<sub>2</sub>MH.<sup>267</sup>

## 9.9 Cross-coupling of Unsaturated Organic Substrates

NbCl<sub>3</sub>(DME) is found to be a useful reagent for the intermolecular pinacol coupling of aliphatic aldehydes

RCHO to give diols RCH(OH)–RCH(OH). The high anti-diastereoselectivity (*dl meso* ≥ 9/1) is consistent with the mechanism involving an insertion of the oxo-group into the Nb–C bond of the intermediate niobiooxirane [Nb](η<sup>2</sup>-C, O-CHR=O).<sup>268</sup>

Reaction of Cp\*<sub>2</sub>Nb<sup>III</sup>(=O)H with excess isocyanate PhN=C=O gave a mixture of heterocycles (PhNCO)<sub>2</sub> and (PhNCO)<sub>3</sub>.<sup>269</sup> Cp\*Ta<sup>III</sup>(1-phenylallyl)<sub>2</sub> is also a catalyst for the dimerization of isocyanates RN=C=O (R = Et, Bu<sup>t</sup>, Cy) to (RNCO)<sub>2</sub>.<sup>198</sup>

Treatment of tantalum-alkyne complexes, prepared in situ from TaCl<sub>5</sub>, Zn and RC≡CR (R = n-C<sub>5</sub>H<sub>11</sub>), with the lithio-imine Li–N=CR'Me (R' = n-C<sub>8</sub>H<sub>17</sub>), followed by aqueous NaOH, gives primary (*E*)-allylic amines *E*-RCH=CR–CR'Me(NH<sub>2</sub>).<sup>270</sup> Treatment of these complexes with the terminal alkyne R''C≡CH (R'' = n-C<sub>6</sub>H<sub>13</sub>), followed by aqueous NaOH, yields tetrasubstituted benzene derivatives (**99a–d**).<sup>271</sup>

Ta reagents 'Ta–Nu', prepared by the transmetalation of organotin compounds (Bu<sup>n</sup>Sn–Nu) with TaCl<sub>5</sub>, promote the conjugate allylation of enones RC(=O)CH=CR'R''. The reactions, followed by treating with MeOH, give RC(=O)CH<sub>2</sub>CR'R''(Nu) (e.g., R = Me, R' = Ph, R'' = H, Nu = allyl).<sup>272</sup>

TaCl<sub>5</sub>–SiO<sub>2</sub> has been used as an efficient Lewis acid (*see Lewis Acids & Bases*) catalyst for the three-component coupling (*see Coupling*) of aldehydes or ketones, aromatic amines, and HOP(OEt)<sub>2</sub> to produce α-amino phosphonates. Thus, coupling reaction of PhCH=O, PhNH<sub>2</sub>, and HOP(OEt)<sub>2</sub> is catalyzed by TaCl<sub>5</sub>–SiO<sub>2</sub>, forming PhNHCH(Ph)–P(=O)(OEt)<sub>2</sub> in 90% yield.<sup>273</sup>

## Glossary

**Activation:** a characteristic phenotypic change in immune cells (including macrophages) upon specific stimulation by cytokines and/or bacterial products that renders them able to recognize and kill foreign or abnormal cells, through mechanisms that can involve production of  $\cdot\text{NO}$

**Agonist:** a general biological term for certain substances that activate a given biological response

**Autocrine:** a mechanism whereby one cell affects itself

**Calmodulin:** a soluble protein present in all types of cells that binds calcium. The calcium complex binds to and affects the activity of a variety of enzymes

**Cellular immunity:** recognition and neutralization of foreign cells, pathogenic organisms, and abnormal host cells through a mechanism that is typically triggered by antibody but, once activated, does not involve antibody; also termed nonspecific immunity

**Complement:** a series of proteins that bind to foreign antigens or cells, and that can induce lysis or activate other immunological processes

**Cytokines:** a family of small soluble proteins that are 'immune hormones', that is, they are produced under specific

conditions of immune activity and act to transmit messages from one immune cell to another. They are extraordinarily important to the control of the complex repertoire of the entire immune defense mechanism

**Cytostatic:** does not kill cells, but inhibits their proliferation (division and growth)

**Cytotoxic:** kills cells

**Cytotoxic activated macrophages (CAMs):** macrophages that have been treated either in vivo or in vitro by exposure to a combination of bacterial products (such as endotoxin) plus cytokines (particularly interferon- $\gamma$ ), rendering them able to kill or damage abnormal cells (cancerous or infected with pathogenic microbe or virus) or pathogen. An important component of the CAMs armature for this cytotoxic mechanism is production of  $\cdot\text{NO}$

**Cytotoxic effector:** substances produced by certain immune cells (such as  $\cdot\text{NO}$ ) that result in killing of their targets, typically abnormal cells or invading pathogen

**Denitrification:** the microbial transformation of nitrite and nitrate to  $\text{N}_2$

**Digitonin:** a mild detergent that permeabilizes the plasma membrane of most mammalian cells without affecting organelles such as the mitochondria

**Endothelial cells:** cells that line the inside (lumen) of the blood vessels, that produce  $\cdot\text{NO}$  for the regulation of blood pressure

**Endothelial-derived relaxing factor (EDRF):** a small, diffusible molecule that is released by the vascular endothelial cell and diffuses to the overlying smooth muscle cell, where it induces relaxation and resulting vasodilation. EDRF is either  $\cdot\text{NO}$  alone or a bound form of  $\cdot\text{NO}$

**Endotoxin:** a molecular component of certain bacteria that is recognized by certain cells of the immune system (most especially macrophages) and triggers the activation of many immune functions, including synthesis of  $\cdot\text{NO}$ ; also called lipopolysaccharide

**EPR:** electron paramagnetic resonance spectroscopy

**Guanylyl cyclase:** a heme-containing enzyme that is stimulated by  $\cdot\text{NO}$  and results in the formation of cyclic guanosine monophosphate, which signals a variety of processes in the cell including relaxation of smooth muscle cells in the vasculature

**Hepatic:** pertaining to the liver

**Homodimers:** a protein composed of two identical protein subunits tightly bound to each other

**Humoral immunity:** immune defense mechanisms that involve the participation of antibodies against foreign antigens; also termed specific immunity

**Hypotension:** low blood pressure

**Immune surveillance:** the hypothesis that cancerous cells are continually developing, but that the body's immune system normally is capable of identifying and removing these dangerous cells

**Immunohistochemical method:** a method using specific antibodies to detect the presence and microscopic location of

individual proteins or groups (e.g. nitrotyrosine) microscopically in tissues or cells

*Interferons:* a class of cytokines that were originally discovered because they interfered with viral replication inside mammalian cells, but are now known to perform many other functions, including transmission of information from one immune cell to another; interferon- $\gamma$  is the most potent cytokine known to induce  $\cdot\text{NO}$  formation by activated macrophages

*Interleukins:* a subset of the cytokines, denoted by the designation IL-1, IL-2, and so on, and each has specific functions in regulating the immune reaction

*Lymphotoxin:* a cytokine, similar to tumor necrosis factor

*Lipopolysaccharide:* a molecular component of certain bacteria, that is recognized by certain cells of the immune system (most especially macrophages) and triggers the activation of many immune functions, including synthesis of  $\cdot\text{NO}$ ; also called endotoxin

*Lymphocytes:* immune cells that orchestrate the immune response

*Macrophages:* a phagocytic cell of the immune system that performs many functions critical to defense against foreign or pathogenic organisms

*Murine:* from a mouse

*Necrosis:* a type of cell death or nonspecific tissue decay

*Neoplastic:* cancerous

*Neurotransmitter:* a molecular messenger that is released by one cell of the nervous system and induces a specific signal in another cell

*Neutrophils:* a phagocytic immune cell, whose central function is to kill invading organisms

*Nitrovasodilators:* certain compounds such as nitroglycerine, nitroprusside, and isosorbide dinitrate, that act to cause decrease in blood pressure by releasing  $\cdot\text{NO}$

*Nonspecific immunity:* recognition and neutralization of foreign cells, pathogenic organisms, and abnormal host cells through a mechanism that is typically triggered by antibody but, once activated, does not involve antibody; also termed cellular immunity

*Paracrine:* a mechanism whereby one cell affects another

*Peritoneal cavity:* the body cavity that houses the organs of the gut

*Phagolysosome:* a membrane-surrounded compartment in phagocytic cells where certain products are assembled for further processing and secretion; the pH of this compartment is low (4 or less)

*Posttranslational Protein Modification:* a mechanism of biological control of protein activity by covalent modification after protein synthesis

*Reactive Oxygen Species:* intermediates of  $\text{O}_2$  between  $\text{O}_2$  and  $\text{H}_2\text{O}$  that are involved in oxidative cellular injury ( $\cdot\text{O}_2^-$ ,  $\text{H}_2\text{O}_2$ ,  $\cdot\text{OH}$ )

*Sepsis:* a serious infection that results in the presence of bacteria and bacterial products in the circulation

*Septic shock:* a serious and life-threatening clinical condition where massive bacterial products and bacteria in the circulation results in an excessive immune response

*Specific immunity:* immune defense mechanisms that involve the participation of antibodies against foreign antigens; also termed humoral immunity

*Transformed:* a term applied to mammalian cell cultures that have become 'immortalized', that is, they grow and divide and thus resemble cancerous cells

*Tumor necrosis factor (TNF):* a multifunctional cytokine that is capable of specifically stimulating certain cells to perform a wide variety of immune functions, and also induces a 'suicide' response in many abnormal cells (cancerous, infected with pathogenic microbe or virus)

*Vascular smooth muscle cells:* the cells that surround the blood vessels and control blood pressure by relaxing or contracting in response to specific signals, including  $\cdot\text{NO}$

*Vascular tone:* the degree of contraction of the vascular smooth muscle cells that regulates blood pressure

*Vasodilation or vasodilatation:* expansion of the blood vessels as a result of relaxation of the smooth muscle cells that overlie the vessels, resulting in decreased blood pressure

## Abbreviations

$\text{BH}_4$  = Tetrahydrobiopterin; CAM = Cytotoxic activated macrophage; cNOS = Constitutive nitric oxide synthase; CPR = Cytochrome P450 reductase; EDRF = Endothelial-derived relaxation factor; EPR = Electron paramagnetic resonance spectroscopy; IL-1 = Interleukin-1; iNOS = Inducible nitric oxide synthase; LPS = Lipopolysaccharide, or endotoxin; NMMA =  $\text{N}^G$ -monomethyl-L-arginine; NOS = Nitric oxide synthase; ROS = Reactive oxygen species; SOD = Superoxide dismutase; TNF = Tumor necrosis factor.

## 1 INTRODUCTION

As documented by the selection of nitric oxide ( $\cdot\text{NO}$ , nitrogen monoxide) by *Science* as 'Molecule of the Year' for 1992, followed by the 1998 Nobel Prizes for Physiology or Medicine, research into the remarkable and multiple roles of  $\cdot\text{NO}$  in biology has exploded since 1987 (with nearly 70 000 publications, most appearing within the last five years). It is probably true that  $\cdot\text{NO}$  is involved in one way or another in virtually every common pathophysiological state by virtue of its importance in the normal maintenance of many important physiological phenomena (such as blood pressure, neurotransmission, and gastrointestinal function) as well as in the host response to disease (immune and inflammatory stimulation, cancer, and cardiovascular disease) (Figure 1).

**Figure 1** Schematic representation of the three major roles of  $\cdot\text{NO}$  in mammalian biology. (a) As the messenger responsible for vascular dilation (EDRF),  $\cdot\text{NO}$  is produced in the endothelial cell (EC) that line the lumen of the blood vessels upon stimulation with certain specific agonists (and also, although not shown in the diagram, physical changes in the flow of blood). These agonists act by stimulating an influx of  $\text{Ca}^{2+}$  into the EC, which binds to calmodulin and this calcium-calmodulin complex binds to the constitutive nitric oxide synthase (cNOS), which catalyzes the formation of  $\cdot\text{NO}$  and citrulline from L-arginine. The  $\cdot\text{NO}$  diffuses into the surrounding vascular smooth muscle cell (SMC), and stimulates the enzyme guanylyl cyclase to produce cyclic GMP cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP); this stimulation occurs because  $\cdot\text{NO}$  binds to a heme group, specifically required for maximal enzymatic activity. The increase in cGMP acts upon the contractile apparatus of the SMC (by a largely unknown mechanism) to induce relaxation. (b) In the immune system, particularly the macrophage, activation by exposure to bacterial products and/or cytokines induces the de novo transcription and translation of the gene for the inducible isoform of nitric oxide synthase (iNOS), which produces  $\cdot\text{NO}$  and citrulline from L-arginine in a largely calcium-independent manner. The  $\cdot\text{NO}$  interferes with the normal energetic metabolism of both the macrophage and the target cell, by inhibiting iron-containing enzyme function. (c) In the neural system, the production of  $\cdot\text{NO}$  resembles that for the vascular system in that  $\cdot\text{NO}$  is synthesized by a constitutive NOS (although it is different from the enzyme in EC cells) in response to increased internal  $\text{Ca}^{2+}$ ; however, the signals that trigger this response are certain neurotransmitters, that are released by the presynaptic terminal and diffuse to another adjacent cell at the postsynaptic terminal.  $\cdot\text{NO}$  produced in the postsynaptic cell affects that cell and possibly also the presynaptic cell in a 'feedback' manner, in both cases through the heme-mediated stimulation of guanylyl cyclase

This article is written as a general review that is intended to bridge many interdisciplinary gaps ranging from chemistry, biochemistry, and spectroscopy to physiology, neuroscience, immunology, and biomedicine. Because of the extraordinary range of scientific literature on  $\cdot\text{NO}$ , it is possible to obtain great insight into this unique molecule's multiple actions by combining concepts on this multifaceted molecule from these disciplines. The trade-off for such an approach, however, is that a sufficient amount of background material must be provided for the nonspecialist in each area. Although we will provide the reader with appropriate citations for entry into the original literature and reviews in the many fields that have been affected by this fast-moving area, our focus will be upon what is presently known about the molecular mechanisms of action of  $\cdot\text{NO}$  in mammalian physiology and pathophysiology, much of which has come from studies in immunology. We will not attempt to cover the entire range of biological roles of  $\cdot\text{NO}$ , which is covered in many books and reviews,<sup>1-38</sup> including

methods for measurement and preparation and handling of  $\cdot\text{NO}$ <sup>39-43</sup> and the chemistry and biochemistry of its reactions with biological targets.<sup>44-47</sup> There are also three books of proceedings of international conferences that have appeared on the biology of  $\cdot\text{NO}$ ,<sup>48-50</sup> and volumes 268, 269, 301, and 359 of *Methods in Enzymology* are devoted to various aspects of  $\cdot\text{NO}$  chemistry and biochemistry. There are also books dealing with metal-nitrosyls<sup>51</sup> and their electron paramagnetic resonance (EPR) spectroscopy<sup>52</sup> as well as various biomedical aspects of  $\cdot\text{NO}$ .<sup>53-55</sup> In addition, a recent book on  $\cdot\text{NO}$ , its chemistry, and its biochemistry has appeared<sup>56</sup> and is a superb resource, especially for chemists interested in the biological roles of  $\cdot\text{NO}$  and the basics of its mechanistic actions. Finally, Carl Djerassi has written an entertaining fictional (but chemically informative and historical) novel entitled ' $\cdot\text{NO}$ '.

As we shall see, a thorough appreciation for the chemistry and biochemistry of  $\cdot\text{NO}$  is essential for any fundamental understanding of its critical roles in a multitude of biologically

and medically important areas and can provide important new insights and tools for its study.

## 2 NITRIC OXIDE CHEMISTRY

Owing to its unpaired electronic configuration, the reactions of  $\cdot\text{NO}$  with the highest rate constants involve either its association with a transition metal ion or recombination reactions with other radical and paramagnetic species. Iron is the most prevalent transition metal ion, being required for a variety of essential functions. In addition, several iron-containing proteins such as hemoglobin, myoglobin, the cytochromes P450, and cytochrome oxidase are specifically designed to bind  $\text{O}_2$  and since  $\cdot\text{NO}$  is similar in structure, it can bind to these proteins as an oxygen surrogate (see *Iron: Heme Proteins & Dioxygen Transport & Storage, Iron: Heme Proteins, Mono- & Dioxygenases, Cytochrome Oxidase*). Under physiological conditions, most heme in hemoglobin is oxygenated. In this case,  $\cdot\text{NO}$  reacts extremely rapidly, essentially 'extracting' the equivalent of superoxide from the ferroheme and generating nitrate and the oxidized heme:<sup>57–59</sup>

Quantitatively, this reaction probably represents the major *in vivo* route for  $\cdot\text{NO}$  conversion into stable metabolites.<sup>60</sup>  $\cdot\text{NO}$  also reacts with oxygen complexes of other metallo-proteins, including lipoxygenase<sup>61</sup> and myeloperoxidase (see *Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases*).<sup>62,63</sup> When  $\cdot\text{NO}$  encounters hemoglobin in the reduced deoxy state (in the absence of  $\text{O}_2$ ), it binds to the heme iron atom in a fashion very similar to that of  $\text{O}_2$ . Under physiological conditions, this reaction is probably not functionally relevant given the respective concentrations of  $\text{O}_2$  and  $\cdot\text{NO}$ . However, the inhibitory effects of  $\cdot\text{NO}$  on cytochrome oxidase, involving binding to both heme and copper, may have important regulatory effects on mitochondrial electron transfer<sup>34</sup> and also diffusion of  $\cdot\text{NO}$  and  $\text{O}_2$  away from the blood vessel.<sup>64</sup>

In addition to hemoproteins, the other major metabolically active pool of intracellular iron is the nonheme iron-sulfur proteins (see *Iron–Sulfur Proteins*), which function primarily as electron carriers, most especially in the mitochondrial electron transfer chain. *In vitro* treatment with  $\cdot\text{NO}$  has been shown to result in conversion of the iron in these clusters into dinitrosyliron thiol complexes  $((\text{RS})_2\text{Fe}(\text{NO})_2)$ .<sup>65</sup> As described in more detail below, these complexes exhibit a characteristic EPR signal, which has been observed in both  $\cdot\text{NO}$ -producing activated macrophages and their tumor cell targets, suggesting that such complexes may also be formed *in vivo*.

In addition to transition metals,  $\cdot\text{NO}$  also reacts with biological radicals.  $\cdot\text{NO}$  reacts with dioxygen in aqueous

solution via a fairly complex reaction to eventually produce nitrous acid (called autoxidation) with an overall stoichiometry:

The kinetic expression for  $\cdot\text{NO}$  autoxidation is rate =  $4k[\cdot\text{NO}]^2[\text{O}_2]$  with  $k = 2\text{--}2.9 \times 10^6 \text{ M}^{-2} \text{ s}^{-1}$ .<sup>66–68</sup> Thus, for physiological concentrations of  $\cdot\text{NO}$  (1–50 nM) the consumption of  $\cdot\text{NO}$  via autoxidation is slow (half-life 2–100 h) and will not account for the loss of significant amounts. However, this reaction may have enormous biological consequences as it results in the formation of species with potent biological activities. In addition, this reaction is accelerated by a factor of nearly 300-fold (on a per volume basis) when it occurs in hydrophobic compartments such as membranes.<sup>69</sup>

In contrast, the reaction of  $\cdot\text{NO}$  with superoxide is extremely rapid ( $k = 1.9 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ ):<sup>70</sup>

After much confusion over the past 10 years, it is now clear that in aqueous buffer in the absence of another reactant, peroxynitrous acid ( $\text{ONOOH}$ ,  $\text{p}K_a = 6.8$ ) undergoes two subsequent reactions, isomerization to produce nitrate (yield 71%) and homolysis to produce hydroxyl radical ( $\cdot\text{OH}$ ) and nitrogen dioxide ( $\cdot\text{NO}_2$ ) (yield 29%).<sup>71</sup> Both of these species are highly oxidizing and much speculation has been directed toward their involvement in biologically damaging actions of  $\cdot\text{NO}$  production (see below). However, under biological conditions, peroxynitrite will undergo at least two other reactions long before isomerization and homolysis, two-electron oxidation of cellular thiol (forming the sulfenic acid and nitrite),<sup>72</sup> and reaction with  $\text{CO}_2$  to form the nitrosoperoxocarbonate anion ( $\text{ONOOCO}_2^-$ ). This extremely short-lived species undergoes either heterolytic scission, producing nitrate and  $\text{CO}_2$  (67% yield) or homolytic scission producing  $\cdot\text{NO}_2$  and the carbonate anion radical ( $\cdot\text{CO}_3^-$ ) (33% yield).<sup>73</sup> Thus, in the biological milieu, reaction of  $\cdot\text{NO}$  with superoxide generates two potent oxidants, linking  $\cdot\text{NO}$  and cellular oxidizing species with mild activity to form potent new stressors. The production of both  $\cdot\text{NO}$  and  $\cdot\text{O}_2^-$  are deliberately upregulated in locations of inflammatory stimulation, indicating that this reaction plays a key role in oxidative stress (and also, perhaps, signaling).

$\text{NO}$  also undergoes radical recombination reactions. Reaction with  $\cdot\text{CO}_3^-$  yields  $\text{CO}_2$  and  $\text{HNO}_2$ .<sup>74</sup> The reaction with  $\cdot\text{NO}_2$ , produced from the reaction of  $\cdot\text{NO}$  with both  $\text{O}_2$  and  $\cdot\text{O}_2^-$ , yields the potent nitrosating agent nitrous anhydride ( $\text{N}_2\text{O}_3$ ).<sup>75</sup>  $\text{N}_2\text{O}_3$  reacts with water, which, in addition to the nitrosation reaction, generates nitrite. The two most important targets for nitrosation are amines and thiols.<sup>76</sup> In the case of amines, the subsequent chemistry is different for each type of amine. For primary amines, the nitrosamine is the initial

product that rapidly forms a diazo compound. The diazo is an excellent leaving group, which results in the formation of an alcohol and so the net result is the conversion of a primary amine into an alcohol. For secondary amines, the nitrosamine is stable but is metabolized in cells to yield a variety of highly reactive and mutagenic species.<sup>77</sup> Correspondingly thiols also are excellent nitrosation acceptors, yielding nitrosothiols. As described below, this covalent modification has been proposed to be an important mechanism of posttranslational protein modification. In addition,  $\cdot\text{NO}$  (and also  $\cdot\text{NO}_2$ ) reacts with radical species produced by one-electron oxidation. One important species is the initial product of lipid peroxidation (e.g. peroxy species), which results in the formation of several different nitrolipid species.<sup>23</sup> This action represents a potent antioxidative activity of  $\cdot\text{NO}$  and  $\cdot\text{NO}_2$  since it results in radical chain termination, and there is also recent evidence that these species may possess specific regulatory and anti-inflammatory signaling activity as well.<sup>23,78</sup> Finally,  $\cdot\text{NO}_2$  will recombine with tyrosyl radical thus resulting in the formation of stable nitrotyrosine. Nitrotyrosine can also be formed from an ill-defined reaction of peroxynitrite with metals<sup>79</sup> and also metals (including peroxidases) in the presence of nitrite and  $\text{H}_2\text{O}_2$ .<sup>80,81</sup>

The biological transformations of  $\cdot\text{NO}$  described above are all oxidative. Although chemical studies have shown that reduction of  $\cdot\text{NO}$  to form nitroxyl ( $\text{HNO}$ ) can occur via some biochemical mechanisms (e.g. superoxide dismutase (SOD),<sup>82</sup>  $\cdot\text{NO}$  synthase,<sup>83</sup> mitochondrial metabolism,<sup>84</sup> and reaction of nitrosothiols with thiols<sup>85</sup>), little evidence has been presented to suggest that functionally relevant quantities of nitroxyl are produced in vivo.<sup>86,87</sup>

### 3 NITRIC OXIDE AND BIOLOGY PRIOR TO 1980

Nitric oxide is one of the most extensively investigated molecules in inorganic and bioinorganic chemistry, having been originally discovered in 1620 by the Belgian chemist Jan Baptist van Helmont when an 'air' was generated upon pouring nitric acid over metal filings.<sup>88</sup> Priestley is generally credited with the original discovery of  $\cdot\text{NO}$ ,<sup>89</sup> and this is correct in the sense that he recognized it as distinct from other gases. It is noteworthy that Dalton utilized the reactions of  $\cdot\text{NO}$  with air to perform the first accurate determination of the content of oxygen in the atmosphere,<sup>90</sup> which of course requires a proper appreciation of the concepts of reaction stoichiometry. Because of its close resemblance to dioxygen (one atomic number different) and its paramagnetism (15 total electrons),  $\cdot\text{NO}$  has been used extensively as an  $\text{O}_2$  surrogate to probe the metal environment of a variety of metalloproteins. In particular,  $\cdot\text{NO}$  has been shown to bind to  $\text{Fe}^{2+}$  in heme-containing oxygen transporting proteins (*see Iron: Heme Proteins & Dioxygen Transport & Storage*) in a fashion nearly identical to  $\text{O}_2$ , with the important

consequence of rendering the complex paramagnetic and so visible by EPR spectroscopy.<sup>91</sup> Because the unpaired electron assumes appreciable iron d orbital character, analysis of the EPR characteristics of hemoprotein nitrosyl complexes yields a great deal of information on both the ligand binding environment around the heme and on the conformational states of the protein (*see Iron Porphyrin Chemistry*). Indeed, much of the classic work delineating the ligand-induced T to R allosteric transitions in hemoglobin were based on EPR studies of nitrosylhemoglobin,<sup>92,93</sup> first described in detail by Hideo Kon in a classic paper in 1968.<sup>94</sup>

Prior to the 1980s, studies on the biological roles of  $\cdot\text{NO}$  were confined almost exclusively to five areas: its actions as an atmospheric pollutant,<sup>95</sup> as a potent stimulator of the mammalian enzyme soluble guanylyl cyclase<sup>96</sup> (which presaged its roles as an intercellular messenger as described below), its properties as a food preservative,<sup>97</sup> and its roles in the microbial nitrogen cycle<sup>98</sup> and in the actions of certain nitrogen-containing carcinogenic compounds.<sup>95</sup> However, as described in more detail below, there was EPR evidence for endogenous nitrosyl production of unknown origin in mammals in the late 1960s and early 1970s. In an early study published in 1916, Mitchell, Shonle, and Grindley<sup>99</sup> provided evidence that more nitrate is excreted in the urine of Man than is ingested, suggesting the presence of an endogenous mechanism for production of inorganic nitrogen oxides. This one paper presaged the remarkable discoveries of  $\cdot\text{NO}$  in mammalian biology that occurred more than 60 years later.

Data published in the 1970s<sup>100,101</sup> indicated that  $\cdot\text{NO}$  may be a protein-bound (although probably not freely released) intermediate in the assimilatory reduction of nitrite to ammonia in plants. Nitrite and nitrate, the one- and three-electron oxidation products of  $\cdot\text{NO}$ , respectively, are the precursors for microbial denitrification, which is the reduction of these nitrogen oxides to  $\text{N}_2$ . Early reports described a red haze over molasses vats where denitrification occurs, suggesting  $\cdot\text{NO}$  production and subsequent oxidation to  $\cdot\text{NO}_2$  and  $\text{N}_2\text{O}_4$ .<sup>102</sup>  $\cdot\text{NO}$  production was also observed in soil samples during denitrification,<sup>103</sup> and in extracts of certain denitrifying bacteria<sup>104–106</sup> and purified heme-containing nitrite reductases.<sup>107–109</sup> As described in several studies,<sup>110,111</sup> it is only recently that  $\cdot\text{NO}$  has been shown to be a true intermediate in this process, as opposed to a transient, protein-bound and only slowly releasable intermediate, as mentioned above for plants.

### 4 CELL-MEDIATED IMMUNITY, CYTOTOXIC ACTIVATED MACROPHAGES, AND CYTOKINES

As we will describe in more detail below,  $\cdot\text{NO}$  has been shown to play an important role in (among other areas) mammalian immunology, and it is these studies that have provided most of the information about the molecular

mechanisms of  $\cdot\text{NO}$  effects upon cells (the central focus of this article). In this section, we provide a brief overview for the nonspecialist of the principal components of cellular immunity specifically related to  $\cdot\text{NO}$ ; readers familiar with this area should skip to the next section.

There are two ‘arms’ to the immune defense mechanism. Humoral (or specific) immunity, the most familiar, is the production of specific antibody to foreign antigen, which triggers a panel of different immune responses including lysis of invading cells by the complement cascade and opsonization (specific adsorption of antibody or complement components to the foreign material), which enables recognition by specific phagocytosing cells that engulf and inactivate the antigen. No detailed studies have linked  $\cdot\text{NO}$  to the mechanisms of antibody production.

Cellular (or nonspecific) immunity, on the other hand, does not involve the active participation of antibody, although antigenic stimulation activates it.<sup>112</sup> The historical development of the concept of nonspecific immunity lies in studies carried out in the 1950s and 1960s, which demonstrated that once an immune reaction occurs against a specific antigen, oftentimes certain cells of the immune system (most especially the macrophage) become ‘activated’ and are capable of recognizing and killing not only the pathogen that initiated the response but also unrelated organisms.<sup>113,114</sup> Remarkably, isolated macrophages that have been activated in vivo by infection with microbes and intracellular pathogens (such as *Corynebacterium parvum*, Bacillus Calmette-Guérin, or *Toxoplasma*) are capable of inactivating in vitro not only the pathogen that initiated the activation, but also unrelated pathogenic microbes, viruses, and even tumor cells. Indeed, Hibbs, in particular, has championed the notion that this killing of tumor cells by macrophages serves as an ‘immune surveillance’ mechanism whereby cancerous transformation is continually opposed in vivo.<sup>115</sup> Subsequent research demonstrated that purified components of bacterial cell walls (including lipopolysaccharide (LPS) from gram-negative organisms, also called endotoxin) will replace intact microbes in inducing this cross-resistance.<sup>112</sup>

At the turn of the century, Dr. William B. Coley, a young surgeon in New York City, made the remarkable discovery that injection of live or inactivated pathogenic bacteria into patients with otherwise incurable cancers would oftentimes induce dramatic necrosis (a specific type of cell death) and regression of the tumors.<sup>116,117</sup> Owing to a number of factors including lack of standardization of the potency of the bacterial injections, toxic side effects, variability and sometimes total lack of effect, and the simultaneous advent of radiotherapy, these intriguing results were not followed up until much later.

In 1975, Lloyd Old and colleagues discovered that transfer of serum from the blood of donor mice that had been previously injected with endotoxin into recipient mice harboring tumors would induce necrosis of the tumors.<sup>118</sup> They dubbed the transferrable substance responsible ‘tumor necrosis factor’, or TNF. Remarkably, TNF was also shown to

induce killing in vitro of two different neoplastic cell lines in tissue culture, but had no effect on normal mouse embryo fibroblast cultures. TNF is now known to be a member of an extraordinarily important family of small, soluble proteins called cytokines.<sup>119</sup> These proteins (most of which have been cloned and pure recombinant proteins are now available) function as ‘immune hormones’, and act as messengers to relay information between different cells involved in the immune response. In this capacity, cytokines orchestrate the incredibly complex immune response to infection and inflammation. In addition, several cytokines (including TNF, interferons  $\alpha$  and  $\gamma$ , interleukin- $1\beta$ , and lymphotoxin) are capable of inducing a ‘suicide’ response in vitro in cultured cells that are abnormal (infected with virus or pathogenic microbe, or transformed to a cancerous phenotype). Because this effect obviously does not involve antibody, cytokines are usually considered key components of nonspecific immunity; however, this distinction is not strict because antibody production is also regulated by cytokine production and by cell-specific responses to specific cytokines.<sup>112</sup> Cytokines act by binding to specific receptors on the surface of the responding cell, and act via receptor-mediated signal transduction. Different cells have different receptors for different cytokines, and there can be considerable interaction between different cytokine actions on even the same cell. The result of this complexity is redundancy, synergism, or antagonism of different cytokine effects on a given cell type, conferring exquisite control over the signals transmitted depending on the cytokine(s) present and the cell type as target. Nitric oxide plays an important role in many cytokine actions on isolated cells, as well as on the nonspecific mechanism of macrophage injury and killing of pathogens and tumor cells.

## 5 METABOLIC BASIS OF ACTIVATED MACROPHAGE CYTOTOXICITY TOWARD TUMOR CELLS: STUDIES PRIOR TO 1987

What are the specific intracellular derangements that occur in target cells (specifically, tumor cells) in response to activated macrophages? In 1980, Krahenbuhl<sup>120</sup> studied the in vitro (in culture) effects of murine cytotoxic activated macrophages (CAMs, produced by injection of killed *C. parvum*) on EMT-6 cells, a murine cell line originally derived from explantation of a mammary tumor. These and subsequent studies on the mechanism of CAM-induced injury were greatly facilitated by the fact that this and certain other tumor cell lines are ‘injured’ by CAMs (do not proliferate) but not ‘killed’ (do not lyse). He observed a dramatic and early (within 2 h) inhibition of DNA synthesis in the CAM-injured EMT-6 cells. Shortly thereafter, Granger, Taintor, Cook, and Hibbs<sup>121</sup> examined murine L1210 tumor cells after incubation with macrophages isolated from the peritoneal cavity of mice after they had been pretreated with endotoxin to induce the activated state. Like EMT-6 cells, CAMs are cytostatic against L1210 cells but not cytotoxic.

The striking results revealed that survival of the L1210 cells after CAM coinubation exhibited an absolute requirement for exogenous glucose in the medium, whereas uninjured L1210 cells had no such requirement. The ability of other sugars to substitute (mannose and fructose) correlated quantitatively with their capacity to support glycolytic metabolism, and inhibition of glycolysis with 2-deoxyglucose prevented the ability of glucose and mannose to prevent eventual lysis of the cells. Also, unlike control cells (not pretreated with CAMs), injured cells exhibited no Pasteur effect, meaning lactate production was the same in the presence or absence of oxygen. Finally, oxygen consumption by the injured L1210 cells was 85% inhibited compared to the control cells. These results suggested that CAMs induce an inhibition in mitochondrial oxygen consumption leading to energetic deprivation that can be partially alleviated by glycolytic metabolism.

There are several possibilities for the decreased oxygen consumption in CAM-injured L1210 cells, including defects in required substrate uptake from the medium, imbalances in intracellular ion homeostasis, and critical cofactor depletion. In 1982, Granger and Lehninger<sup>122</sup> performed a careful analysis, using now classic techniques, for determining whether the lesion is a direct inhibition of mitochondrial electron transfer. Using digitonin to selectively permeabilize the L1210 plasma membrane (thus allowing direct measurement of mitochondrial respiration with exogenously added substrates) and selective inhibitors and electron donors of segments of the electron transfer chain, it was found that oxygen reduction from NADH and from succinate as electron donors was inhibited in mitochondria in CAM-injured L1210 cells. However, electron transfer to O<sub>2</sub> from  $\alpha$ -glycerophosphate, which donates electrons on the oxygen side of coenzyme Q, or from the addition of ascorbate plus tetramethylphenylenediamine, which donates electrons at the level of cytochrome *c*, was relatively unaffected. This suggests that there is a site-specific malfunction in the mitochondrial electron transfer chain, localized to complexes I (NADH-coenzyme Q reductase) and II (succinate-coenzyme Q reductase). It is important to point out here that these regions of the chain are especially rich in non-heme iron-sulfur centers. Importantly, simple cessation of cell division does not induce mitochondrial inhibition, and the time course of this inhibition resembled that for inhibition of DNA synthesis. In addition, mitochondrial respiration in the presence of oligomycin (an inhibitor of the proton-translocating adenosine triphosphate (ATP) synthase) was low and similar in both untreated and CAM-injured cells, indicating that there is no defect in the energy-coupling ability of the mitochondria but rather a direct inhibition of electron transfer.

In 1984, Hibbs, Taintor, and Vavrin<sup>123</sup> reported that CAMs cause L1210 cells to lose up to 64% of their intracellular iron, and the time course of this release is similar to that of CAM-induced mitochondrial inhibition. In 1986, Drapier and Hibbs<sup>124</sup> showed that aconitase (an iron-sulfur-containing enzyme (*see Iron-Sulfur Proteins*)) is also a target for CAM injury, and that the injured cells recover aconitase activity

upon addition of Fe<sup>2+</sup> to the medium. It was speculated that the inhibition of DNA synthesis may be due to inhibition of ribonucleotide reductase, which catalyzes the rate-limiting step in this pathway and which contains nonheme iron essential for activity. Wharton, Granger, and Durack<sup>125</sup> subsequently found that NADH dehydrogenase and succinate dehydrogenase are depleted of iron, as judged by <sup>55</sup>Fe radioactivity in isoelectric focusing gel slices corresponding to these complexes. These results indicated that iron-sulfur-containing enzymes are important targets for the CAM-induced injury.

## 6 MACROPHAGE PRODUCTION OF NITROGEN OXIDES

In the early 1980s, Tannenbaum's laboratory definitively showed that humans and rats excrete more urinary nitrate than is ingested,<sup>126,127</sup> as originally suggested for humans in the early study by Mitchell *et al.*<sup>99</sup> A clue to the formation of the nitrate came from work by Tannenbaum's group<sup>128</sup> as well as Hegesh and Shiloah<sup>129</sup> who found that urinary nitrate levels are much higher than normal in infants or adults with diarrhea, suggesting an origin related to infection. Indeed, Tannenbaum and colleagues subsequently demonstrated that nitrate levels in rat urine are elevated also by injection of endotoxin.<sup>128,130</sup>

Stuehr and Marletta and colleagues provided key insight into this phenomenon in the mid-1980s by demonstrating that isolated mouse macrophages, when activated *in vivo* by injection with *Mycobacterium bovis* or Bacillus Calmette-Guérin or treated *in vitro* with endotoxin and/or cytokines (including interferon- $\gamma$ ), are stimulated to produce nitrite and nitrate.<sup>131–134</sup> In addition, it was shown that these activated macrophages cause N-nitrosation of morpholine, which is not induced by the addition of nitrite to macrophages that had not been activated.<sup>135</sup> This result suggests that the active agent responsible for N-nitrosation is an active precursor of nitrite + nitrate, and Marletta *et al.*<sup>136</sup> showed that in macrophages  $\cdot\text{NO}$  is indeed the precursor to nitrite and nitrate, which are produced by the reaction of  $\cdot\text{NO}$  with O<sub>2</sub>.

In 1987, Hibbs, Taintor, and Vavrin published a seminal paper in the field of mammalian nitric oxide production.<sup>137</sup> By using a medium that was depleted in specific components, it was found that the formation of nitrite + nitrate in CAMs requires L-arginine, produces L-citrulline, and is inhibited by the L-arginine analog N<sup>G</sup>-monomethyl-L-arginine (NMMA) (Figure 2). Importantly, addition of NMMA prevents not only formation of nitrogen oxides and citrulline but also inhibition of aconitase and DNA synthesis in tumor cells cocultured with the CAMs. Subsequent studies by Hibbs' laboratory demonstrated that the macrophages themselves are also subject to the same L-arginine-dependent damaging effects that occur in the tumor target cells<sup>138</sup> as well as cytokine-treated isolated tumor cells (in the absence of CAMs) under certain conditions.<sup>139,140</sup> Thus, macrophage activation

**Figure 2** Stoichiometry of the enzymatic mechanism of formation of  $\cdot\text{NO}$ , and the structure of a competitive inhibitor, N<sup>G</sup>-monomethyl-L-arginine (NMMA).  $\cdot\text{NO}$  is synthesized by all NOS's by a similar mechanism, involving the NADPH-dependent mixed-function oxidation of a guanidino nitrogen of the amino acid L-arginine (L-arg) to produce L-citrulline (L-cit) and  $\cdot\text{NO}$ . The nonintegral stoichiometries are explained in the text. NMMA inhibits NOS as a competitive inhibitor

or treatment of isolated cells with cytokines under certain conditions involves the deimination of L-arginine to form L-citrulline and an active precursor to nitrite + nitrate that inhibits intracellular iron-containing enzyme function in either tumor target cells or pathogenic organisms (although there are L-arginine-independent effects of CAMs and cytokines<sup>112</sup>). As we shall see, this intermediate is nitric oxide.

## 7 NITRIC OXIDE AS A MESSENGER MOLECULE

Unexpectedly, parallel research in two separate fields, vascular physiology and neurophysiology, converged with these immunological studies in 1987 and 1988, united by the demonstration that the L-arginine-dependent pathway also produces  $\cdot\text{NO}$  as a messenger molecule for intercellular signal transmission. Although there are distinct differences in the enzymological regulation of  $\cdot\text{NO}$  formation when it functions as a cytotoxic effector (immune) versus a messenger (vasodilation and neural signal transmission), the fundamental biochemistry of the formation of  $\cdot\text{NO}$  and its interactions with its targets are similar, namely, synthesis from the mixed-function oxidation of a guanidino nitrogen of L-arginine and cellular effects exerted by interaction with iron-containing proteins.

The vasculature is composed of two principal cell layers, an endothelial cell lining the lumen and a surrounding layer of smooth muscle cells (SMC) (Figure 1). Vascular relaxation/contraction (vascular tone) is effected by relaxation/contraction of the smooth muscle layer. In 1867, Brunton reported the use of amyl nitrite for the treatment of angina.<sup>141</sup> Since that time, nitrovasodilators have been one of the most

commonly prescribed pharmacologic agents, including the compounds nitroglycerin and nitroprusside. These compounds are potent inducers of systemic decrease in blood pressure (hypotension) and their mechanism of action has been a major area of research in cardiovascular physiology. In the 1970s, Murad's laboratory provided convincing evidence that the ability of this heterogeneous class of compounds to induce vasodilatation is determined by their ability to release nitric oxide, either by cellular metabolism or by spontaneous liberation, and stimulate the intracellular synthesis of the messenger molecule cyclic cGMP.<sup>142,143</sup> Craven and DeRubertis showed that  $\cdot\text{NO}$  and  $\cdot\text{NO}$ -liberating compounds stimulate guanylyl cyclase through binding to heme.<sup>144</sup> In 1980, Furchgott and Zawadzki discovered that the endothelial cell layer releases a diffusible substance (termed Endothelial-Derived Relaxing Factor or EDRF) that travels to the overlying smooth muscle cell layer and induces relaxation.<sup>145</sup> Combining these observations with the stimulatory actions of nitrovasodilators, in 1986 Furchgott and Ignarro simultaneously proposed that EDRF is nitric oxide, although no biochemical mechanism was then known to account for the production of  $\cdot\text{NO}$  in mammals.<sup>146,147</sup>

One year later, Ignarro<sup>148,149</sup> and Palmer, Ferrige, and Moncada<sup>150</sup> demonstrated that EDRF, produced by endothelial cells (EC), has properties indistinguishable from  $\cdot\text{NO}$ , using the analytical techniques employed. It was shown soon thereafter that, like Hibbs demonstrated for the activated macrophage, L-arginine is the precursor, L-citrulline is formed, and NMMA inhibits both  $\cdot\text{NO}$  formation and the production of EDRF.<sup>151–153</sup> It is important to point out that there are also other important molecules produced by the endothelium that regulate vascular tone, including the potent prostaglandin prostacyclin and the small peptide endothelin as well as a so far unidentified mediator of dilation *via* smooth muscle cell membrane hyperpolarization.<sup>154</sup> Nevertheless, substantial modulation of blood pressure *in vivo* can be accomplished by administration of agents that activate (nitrovasodilators) or attenuate (NMMA) this mechanism of vasorelaxation.<sup>10,11</sup> The importance of  $\cdot\text{NO}$  in the vascular system was highlighted in 1998 when the Nobel Prize for Physiology or Medicine was awarded to Furchgott, Ignarro, and Murad 'for their discoveries concerning nitric oxide as a signaling molecule in the cardiovascular system'.

The stimulation of soluble guanylate cyclase (sGC) by  $\cdot\text{NO}$  is arguably the most physiologically important reaction of  $\cdot\text{NO}$ . Early work had demonstrated that isolated sGC contains heme, which is a requirement for stimulation by  $\cdot\text{NO}$ , and that various heme species stimulate the activity of the enzyme.<sup>144</sup> Further work has led to the hypothesis that  $\cdot\text{NO}$  stimulates the enzyme by binding to the distal position and inducing formation of a pentacoordinate complex, thus resulting in breakage of the proximal histidine bond to the iron (*see Iron Porphyrin Chemistry*).<sup>155</sup> Although this model still holds generally, there is evidence that  $\cdot\text{NO}$  may also exert a modulatory effect on activity, presumably at a second site, although this point is in contention.<sup>156,157</sup>

In 1988, Garthwaite demonstrated that cultured cerebellar neurons stimulated with the neurotransmitter glutamate release  $\cdot\text{NO}$ , providing an explanation for the previously established glutamate-induced elevation in neuronal cGMP levels<sup>158</sup> (Figure 1). Soon thereafter, it was shown that brain extracts<sup>159</sup> and slices<sup>160,161</sup> synthesize  $\cdot\text{NO}$  from L-arginine. As described in more detail below, these results sparked a series of studies on the physiological and pathological roles of  $\cdot\text{NO}$  in neurotransmission, an area that is one of the most intensely investigated in the biological roles of this molecule.

Remarkably, a critical target of  $\cdot\text{NO}$  is the cytosolic form of aconitase, which in fact possesses either of two biological activities; in one form, which is dominant under conditions of cellular iron depletion, the protein functions as iron regulatory protein-1 (IRP-1) and is a key control in regulation of iron homeostasis (see *Metalloreulation*) by acting as a transcription factor increasing expression of transferrin receptor and ferritin.<sup>162</sup> This form possesses no aconitase activity; however, under conditions of iron repletion the protein acquires aconitase activity and loses IRP-1 activity. The mechanism of this conversion involves the presence (aconitase active, IRP-1 inactive) or absence (aconitase inactive, IRP-1 active) of an intact iron-sulfur center (see *Iron–Sulfur Proteins*). Cellular  $\cdot\text{NO}$  formation, by disrupting the intactness of the iron-sulfur cluster, thus induces a cellular response (in terms of iron homeostasis) similar to iron depletion. Indeed, there is evidence that at least part of the effect of  $\cdot\text{NO}$  on the IRP system is due to its depletion of cellular iron pools.<sup>163–165</sup>  $\cdot\text{NO}$  also activates the iron-sulfur-containing bacterial transcription factor SoxR, which is involved in regulating defensive responses to oxidative stress (see *Iron–Sulfur Proteins*).<sup>166</sup> The precise mechanism of action of  $\cdot\text{NO}$  in protein-bound iron-sulfur centers is not clear, with the three possibilities being disruption of the cluster via direct attack of  $\cdot\text{NO}$ , as described above,<sup>163,167</sup> similar direct disruption via reactive nitrogen oxide products resulting from  $\cdot\text{NO}$  (e.g. peroxynitrite<sup>167</sup>), and loss of activity from nitrogen oxide-induced thiol modification.<sup>168</sup> It is, however, difficult to demonstrate experimentally direct effects of  $\cdot\text{NO}$  (as compared to actions of higher nitrogen oxides) since such a demonstration would require anoxic, unphysiological conditions, which among other effects would dramatically increase the concentration of  $\cdot\text{NO}$ .<sup>64</sup> In any event, it does appear that disruption of iron-sulfur center function can be a deleterious cellular injury since cells possess mechanisms for their repair (see *Iron–Sulfur Proteins*).<sup>123,169,170</sup>

## 8 POSTTRANSLATIONAL COVALENT PROTEIN MODIFICATION BY $\cdot\text{NO}$ -DERIVED SPECIES

Nitrosation of thiols to form nitrosothiols as a result of endogenous  $\cdot\text{NO}$  synthesis can occur for both small molecules such as glutathione and large molecules, especially the

cysteine residues of proteins. In an analogous manner to nitration, not all cellular thiol groups are equally susceptible to nitrosation<sup>171–173</sup> and there is evidence that nitrosation of protein thiols may serve as a mechanism for regulation of protein function.<sup>174</sup> However, a critical unresolved issue is the mechanism of this nitrosation, which is largely unknown.<sup>175</sup> The direct reaction of  $\cdot\text{NO}$  with thiols, which results in disulfide formation, is too slow to be of biological relevance with physiological  $\cdot\text{NO}$  concentrations.<sup>176</sup> Espey *et al.* have demonstrated that under conditions of slight excess of  $\cdot\text{NO}$  production over superoxide production, rapid nitrosative chemistry can occur.<sup>177</sup> Thus, peroxynitrite acts to oxidize a target, which then reacts with  $\cdot\text{NO}$ , presenting a plausible pathway for nitrosothiol formation. Once formed, the nitrosothiol group can be exchanged between thiols via transnitrosation. Therefore following an initial reaction such as nitrosogluthathione (GSNO) formation, different nitrosothiols can readily be formed downstream of the original nitrosation event. The stability of nitrosothiols is also heavily dependent on the nature of the substituent group, generating a large variation in half-lives and corresponding biological effects. Additionally nitrosothiols, in the presence of even trace amounts of transition metals (especially  $\text{Cu}^{1+}$ ), will break down to liberate  $\cdot\text{NO}$ .<sup>178</sup> Overall, there is at present little to no unequivocal evidence for a functional role for thiol nitrosation as a widespread and physiologically significant mechanism of regulation of protein function.<sup>179</sup>

A mechanism of protein thiol nitrosation of special interest is hemoglobin (see *Iron: Heme Proteins & Dioxygen Transport & Storage*), wherein nitrosation of  $\text{cys}\beta\text{-93}$  has been proposed to serve a function as ‘preserver’ of  $\cdot\text{NO}$  biological activity in the face of the very rapid irreversible consumption of  $\cdot\text{NO}$  via oxidation.<sup>180</sup> In addition, since changes in the accessibility of this thiol to covalent modification upon changes in the oxygenation state of hemoglobin has been known for many years,<sup>181</sup> a respiratory cycle has been proposed where uptake of  $\text{O}_2$  and  $\cdot\text{NO}$  are proposed to exhibit positive cooperativity and so hemoglobin will deliver both  $\text{O}_2$  and  $\cdot\text{NO}$  from the lung to  $\text{O}_2$ -deficient tissues.<sup>174,182</sup> However, important mechanistic details regarding formation, movement to the target (smooth muscle cell guanylate cyclase), and vasodilation from the nitrogen oxide species responsible are lacking. This controversy is still very much ongoing, with several recent reviews pro<sup>183,184</sup> and con.<sup>36,185,186</sup> Very recently, a novel interaction between nitrite and deoxyhemoglobin has been reported that could accomplish delivery of  $\cdot\text{NO}$  to tissue that is low in  $\text{O}_2$ .<sup>187</sup>

Metallothionein (MT) is a small protein ( $\sim 6$  kDa) that binds zinc tightly via cysteine residues (see *Metallothioneins*).<sup>188</sup> The ability of these thiolate clusters to bind zinc is dependent on the redox states of the sulfur ligands, with oxidation resulting in expulsion of the zinc ion. Control of zinc homeostasis (see *Metallochaperones & Metal Ion Homeostasis*) is an important regulatory function, as zinc is an essential component of many protein structures including DNA transcription factors and metabolic enzymes. Nitrosation

of the MT cysteine ligands as a result of  $\cdot\text{NO}$  formation releases the chelated metal and so allows  $\cdot\text{NO}$  to regulate zinc concentration.<sup>189</sup> This provides an elegant example of transduction of the nitrosative stimulus from a short-lived redox active species to the more stable, redox inert, zinc ion. In addition to the regulation of iron homeostasis via aconitase this provides another mechanism whereby the effects of  $\cdot\text{NO}$  production can continue to exert an effect on the cell long after the actual stimulus has finished.

## 9 EPR OF BIOLOGICAL IRON-NITROSYL COMPLEXES

Nitric oxide has been a favorite tool of biochemical spectroscopists, dating back to at least 1937 when Keilin and Hartree demonstrated nitrosylation of the heme group of cytochrome *c* (see *Iron: Heme Proteins & Electron Transport*) under anaerobic conditions.<sup>190</sup> Numerous studies have employed  $\cdot\text{NO}$  as an oxygen surrogate for  $\text{O}_2$ -carrying hemoproteins, most especially utilizing the fact that  $\cdot\text{NO}$  binds to the heme ferrous iron in hemoglobin and myoglobin in a configuration essentially identical to  $\text{O}_2$  with the added 'bonus' that the complex is paramagnetic and EPR visible (see *Iron: Heme Proteins & Dioxygen Transport & Storage*). As described in more detail below, these findings provided a spectroscopic tool to examine whole blood by EPR from animals stimulated to produce  $\cdot\text{NO}$  endogenously by immune stimulation or in humans administered  $\cdot\text{NO}$ -donating nitrovasodilators.

The first detailed EPR studies of biological nonheme iron-nitrosyl complexes were carried out primarily by the laboratories of Commoner, Kayushin, and Vanin. Utilizing the results of a study by McDonald *et al.* on small inorganic complexes,<sup>191</sup> the characteristic axial  $g = 2.04$  signal resulting from the exposure of biological samples to  $\cdot\text{NO}$  or  $\cdot\text{NO}$ -generating systems,<sup>192–197</sup> as well as feeding of animals nitrite or nitrate plus or minus iron<sup>196–204</sup> (and in some cases untreated yeast cells<sup>205</sup> or animals<sup>202,206</sup>), was attributed to the formation of complexes of the general formula  $[(\text{RS})_2\text{Fe}(\text{NO})_2]$  with the iron in approximately tetrahedral geometry.<sup>207,208</sup> Similar complexes are formed in cells stimulated by cytokines to produce  $\cdot\text{NO}$  endogenously by  $\cdot\text{NO}$  synthase, as described below. Early studies by Dervartanian *et al.*<sup>209</sup> and Salerno *et al.*<sup>65</sup> demonstrated the appearance of these signals in  $\cdot\text{NO}$ -treated isolated mitochondrial Complexes II and III. Since then, similar signals have been reported for other purified iron-sulfur-containing enzymes (see *Iron–Sulfur Proteins*),<sup>210–212</sup> and numerous studies have shown that this complexation results in destruction of enzymatic activity. Indeed, destruction of the native chromophoric iron-sulfur cluster of *Clostridial* ferredoxin has been used as a spectrophotometric assay to detect cellular  $\cdot\text{NO}$  formation in vitro.<sup>213</sup>

What is the physiological relevance of this damaging reaction in the biological actions of  $\cdot\text{NO}$ ? In the late 1960s Commoner showed the formation of these EPR-detectable complexes in the liver of rats fed carcinogenic compounds in the diet; the signal appeared and then disappeared many weeks prior to the appearance of hepatic tumors and so generated a great deal of interest because of its potential use as an early indication of neoplastic transformation. This conclusion is bolstered by the observation of similar signals (as well as heme-nitrosyl signals) in other tumors of noncarcinogenic compound origin including stably transformed transplantable tumor cells.<sup>214,215</sup> However, Commoner and others subsequently demonstrated that the carcinogen-induced appearance of the  $g = 2.04$  signal is dependent on high dietary nitrate consumption, which is apparently not consistent with an origin of  $\cdot\text{NO}$  from the L-arginine-dependent  $\cdot\text{NO}$  synthase reaction.<sup>216</sup> In addition, it was shown that similar iron-nitrosyl signals are observed in nonspecifically necrotic tissues.<sup>215,217</sup> These results, combined with the lack of indication at that time for a mechanism of mammalian nitrogen oxide synthesis, unfortunately discouraged further research on this interesting phenomenon.

Sodium nitrite is commonly utilized in food preservation.<sup>218</sup> In spite of its known potential for metabolism to carcinogenic nitrosamines, nitrite supplementation is still in widespread use in nutrition because the addition of nitrite (plus a reducing agent such as ascorbate) has two desirable effects: it imparts a red color to meats (primarily a result of the production of nitrosylheme from myoglobin<sup>219</sup>) and, perhaps more importantly, the organism responsible for botulism (*Clostridium botulinum*) is exquisitely sensitive to this treatment.<sup>220</sup> There is indeed a massive literature on the role of  $\cdot\text{NO}$  and its reactions in foods in the nutrition fields and is worthy of scrutiny by researchers in the biological effects of endogenously produced  $\cdot\text{NO}$  in mammalian systems.

Capitalizing on the facts that nonheme iron-sulfur proteins are critically important to the anaerobic metabolism of *Clostridia* in general<sup>221</sup> and the earlier EPR studies showing destruction of these centers by nitrite addition in vitro, in 1983 we performed an EPR examination of whole cells of *C. botulinum* under conditions approximating those during food preservation.<sup>222</sup> We indeed observed the formation of an intense  $g = 2.04$  signal in these cells when treated with nitrite. The facts that the formation of these signals is increased when ascorbate is also added and that the EPR signal from the native intracellular iron-sulfur clusters are concomitantly decreased suggested that the antibotulinal mechanism involves the  $\cdot\text{NO}$ -mediated destruction of nonheme iron-containing enzymes. Although the mechanism of formation of these nonheme iron-nitrosyl complexes may not be as straightforward as direct reaction with iron-sulfur proteins,<sup>211,223</sup> these results indicate that disruption in cellular iron functions by  $\cdot\text{NO}$  complexation is damaging to the cell, a mechanism that is also important when  $\cdot\text{NO}$  is produced by mammalian cells as described below.

In 1990, we<sup>224</sup> and simultaneously Drapier and Henry and colleagues<sup>225</sup> showed that similar  $g = 2.04$  signals are observed in CAMs, and subsequently Drapier and Henry showed similar signals in the injured tumor cell targets of CAMs<sup>212</sup> providing a similar rationale for the destruction of mitochondrial activity that is responsible for the cytostatic and cytotoxic activity of immune-produced endogenous  $\cdot\text{NO}$  synthesis (Figure 1). Although it appears likely that these signals do not in all cases represent direct observation of nitrosylated iron-sulfur proteins (as opposed to other cytosolic forms of nonheme iron), similar signals are indeed observed in several different cell types exposed to inflammatory stimuli.<sup>52,53</sup>

## 10 NITRIC OXIDE SYNTHESIS

Because of the extraordinary range of clinically significant actions of  $\cdot\text{NO}$  in pathophysiology (see below), numerous research groups have been mobilized to investigate the fundamental enzymatic mechanism(s) and regulation of  $\cdot\text{NO}$  synthesis.<sup>30,226</sup> Insight into these mechanisms holds great promise for the design of new effective therapies ranging from carcinogenesis to cardiovascular disease and immunity.

There are three major isoforms of nitric oxide synthase (NOS). The first to be described is termed inducible, because inflammatory agents such as endotoxin and/or cytokines trigger the *de novo* transcription and translation of inducible nitric oxide synthase (iNOS) molecules. It is likely that, at least in rodents, every nucleated cell is capable of being triggered to produce iNOS; the different sensitivities to signals probably lie only in the differing mechanisms of signal transduction between cell types.

The two other major types of NOS are constitutive, that is, present continually, and both produce much smaller quantities of  $\cdot\text{NO}$ . Here,  $\cdot\text{NO}$  acts as a diffusible intracellular and intercellular messenger to stimulate soluble guanylyl cyclase in both the source cell and its neighbors thus effecting both autocrine (one cell affecting itself) and paracrine (one cell affecting another) signal transmission. The two primary physiological functions of  $\cdot\text{NO}$  as a messenger are in control of vascular tone and in neurotransmission.

The first NOS to be isolated and the gene sequenced was the rat cerebellar enzyme, by Bredt and Snyder in 1991.<sup>227,228</sup> Since then, the sequences for all three isoforms have been determined: human brain, human and bovine endothelial, mouse macrophage, and recently the cytokine-inducible NOS from human hepatocytes. There is substantial sequence identity between the same isoforms in different species: rat and human brain (93%<sup>229</sup>) and bovine and human endothelial (94%<sup>230</sup>). The identity between different isoforms (even in the same species) is substantially less, between 50 and 60%.<sup>228,230–236</sup> An exception is the homology between the human hepatocyte and the mouse macrophage enzymes,

which is only 80%,<sup>236</sup> a puzzling result because both enzymes are induced by cytokines and LPS and thus are of the 'inducible' type.

A key observation made by Bredt and Snyder during the purification of the constitutive NOS from rat cerebellum was that this enzyme is greatly stimulated by calcium plus the calcium binding regulatory protein calmodulin (*see Calcium-binding Proteins*).<sup>227</sup> It is now known that the mechanism of stimulation of all constitutive signal-transducing NOS's involves the induction by specific extracellular agonists of increased levels of cytosolic calcium that binds to calmodulin and activates the enzyme. Nathan's laboratory<sup>237</sup> showed that even the highly purified inducible isoform contains tightly bound calmodulin, even though this enzyme is not generally thought to be regulated by intracellular calcium levels. Indeed, the sequences for all three isotypes contain consensus regions for calmodulin binding. Structural and functional analysis has revealed the presence of an autoinhibitory control element in the constitutive enzymes that is released upon calmodulin binding, which is a major factor in the mechanism of calcium regulation of activity.<sup>238</sup>

As illustrated in Figure 2, the basic reaction of  $\cdot\text{NO}$  formation is identical for all three isoforms, involving a three-electron mixed-function oxidation of a guanidino nitrogen of L-arginine to produce citrulline and  $\cdot\text{NO}$ .<sup>239</sup> The reaction consumes three electrons from 1.5 NADPH equivalents and two moles of  $\text{O}_2$ . Two of these oxygen atoms are reduced to water, and one is incorporated into citrulline and one into  $\cdot\text{NO}$ .<sup>240,241</sup> Thus, since only three electrons are donated by NADPH, as pointed out by Stuehr and Griffith<sup>239</sup> L-arginine must provide the fourth electron for the reduction of the two O atoms to  $2\text{H}_2\text{O}$ . The fact that NADPH is an obligatory two-electron donor means that during catalytic turnover the enzyme must cycle between two oxidation states differing by one electron. Indeed, EPR studies of the resting enzyme has revealed the presence of a flavin radical,<sup>242</sup> suggesting that flavins function as electron reservoirs and are capable of stabilizing odd-electron states as in other flavin-containing oxidoreductases.<sup>243</sup>

Beginning with the first NOS sequence published by Bredt and Snyder,<sup>227</sup> all sequences so far reveal consensus regions for the binding of NADPH, FMN, and FAD, and analysis of purified enzymes confirms the presence of one FMN and one FAD per monomer.<sup>239</sup> The stimulation of the enzyme by added FAD suggests weak binding of this cofactor. Thus, NOS is the only mammalian enzyme known besides cytochrome P450 reductase (CPR) that contains both FAD and FMN, as evidenced by the substantial sequence homology between the two enzymes in addition to the consensus regions for flavin binding.<sup>228,239</sup> Indeed, like CPR, NOS reduces several artificial electron acceptor dyes ('diaphorase' activity) as well as molecular oxygen and also cytochrome P450. The deduced molecular weights from the cloned sequences of the endothelial and inducible enzymes from all species examined so far are comparable, approximately 133 kDa; the brain

enzymes from rat and human are larger, 160 kDa, primarily resulting from a substantial N-terminal segment. This segment contains a PDZ domain that targets nNOS for binding to a variety of other proteins within the cell and may well be an important factor in certain diseases such as Duchenne muscular dystrophy.<sup>244,245</sup> All NOS isoforms are composed of specific domains, and catalytic reactivity involves two of these, a reductase domain (containing the NADPH, FMN, and FAD binding sites where electron flow enters the protein and electrons are 'stored' during turnover) and an oxidase domain (containing the substrate, heme, and tetrahydrobiopterin (BH<sub>4</sub>) binding sites). All NOS isoforms are functionally active as homodimers and, remarkably, arranged 'head-to-tail' such that electrons from the reductase domain of one subunit flow to the oxidase domain of the other subunit.<sup>246</sup>

Early studies by Stuehr and Nathan and colleagues<sup>247,248</sup> demonstrated a specific stimulation of NOS activity in crude subcellular fractions by BH<sub>4</sub>, which is true for all purified NOS enzymes to date. BH<sub>4</sub> is important both as a stabilizer of protein conformation and also as an electron transfer component.<sup>226,249</sup> The activity of the enzyme intracellularly can be affected by modulations in cellular BH<sub>4</sub> levels, and this may have important consequences under physiological and pathophysiological conditions.<sup>250–252</sup>

All NOS proteins contain a cytochrome P450-type heme.<sup>242,253–255</sup> Because of the well-established functions of cytochromes P450 in mixed-function hydroxylations (*see Iron: Heme Proteins, Mono- & Dioxygenases*),<sup>256</sup> most attention is now directed toward the potential role of this prosthetic group in carrying out an O-atom transfer reaction in the enzyme (thermodynamically driven by the reduction of O to H<sub>2</sub>O), supported by the inhibition of enzymatic activity by carbon monoxide<sup>242,253,254</sup> and nitrogenous bases,<sup>257</sup> which are heme-binding ligands.

The first step in •NO synthesis is hydroxylation of a guanidino nitrogen of L-arginine to produce N<sup>G</sup>-hydroxy-L-arginine;<sup>239</sup> during turnover a relatively small but significant quantity of this intermediate is released from the enzyme and it is a competent substrate for •NO production. Like L-arginine, •NO formation from N<sup>G</sup>-hydroxy-L-arginine requires the presence of BH<sub>4</sub> and consumes NADPH, but the stoichiometry for NADPH is 0.5 mol per •NO instead of 1.5. Thus, the overall reaction for L-arginine is a two-electron hydroxylation to produce N<sup>G</sup>-hydroxy-L-arginine followed by another that reduces O to H<sub>2</sub>O from one electron from NADPH (probably through the intermediacy of a semiquinone flavin(s)) and one electron from the N<sup>G</sup>-hydroxy-L-arginine and forms •NO and citrulline. The kinetic characterization of each of the individual reaction steps is well under way, and a particularly important concept is that the newly synthesized •NO binds to ferriheme and is an important regulator of activity.<sup>226</sup>

There is increasing attention to the biological importance of mechanisms of •NO formation not involving •NO synthase. Although it has been known for decades that nitrosothiols can produce •NO, and could be important in certain

circumstances as a source for vasodilation,<sup>258</sup> it is only recently that •NO formation from these species has been characterized. Probably the most important mechanism for •NO formation from nitrosothiols in the biological milieu involves metal catalysis.<sup>259,260</sup> Another mechanism, first identified by Furchgott,<sup>261</sup> is via photoactivation; it has recently been demonstrated that this phenomenon is in all probability due to photolysis of nitrosothiol.<sup>262</sup> A major problem with the possibility that nitrosothiol represents a physiologically significant 'reservoir' for •NO (other than under inflammatory conditions where massive amounts of •NO are formed) is that no specific protein-mediated mechanism for •NO formation from nitrosothiol has been identified that could fulfill the requirement for regulation. Another potential mechanism for non-NOS •NO production is through acidification of nitrite, which has attracted attention in regards to acidic compartments biologically (in the stomach and in acidic phagolysosomes),<sup>263</sup> although this has been questioned on kinetic grounds.<sup>264</sup>

## 11 NITRIC OXIDE DIFFUSION

The chemistry of •NO at any specific biological location will be defined not only by the rates of •NO formation but also by the diffusion of •NO from distal locations. Since •NO is freely permeable through biological membranes and exhibits one of the highest diffusion constants known, its actions are not confined to a specific cellular compartment or even a single cell producing it.<sup>265,266</sup> This property places •NO in a unique category of cellular messengers in that it is able to transmit its signal virtually instantaneously after it is produced by •NO synthase. In addition, because of its reactivity, •NO will disappear relatively rapidly and so there is no need for a mechanism of deactivation.

The rapid diffusibility of •NO has critically important implications for its chemistry in the biological setting. The speed with which •NO moves by random diffusion can be illustrated by consideration of its root mean square distance of displacement, which describes the distance a single •NO molecule will move in any time interval based on its diffusion constant D (which is similar for aqueous solution and also tissue (brain)<sup>267</sup>):

$$\langle \Delta \bar{x} \rangle^2 = 2Dt \quad (4)$$

An illustration of the extraordinarily rapid diffusibility of •NO is given by applying this relationship to ask how long, on average, it takes before •NO will escape a cell that produces it. For a cell of 5 μm diameter, equation (4) reveals that, on average, this time will be no more than:

$$t = \frac{(2.5 \mu\text{m})^2}{2 \times 3300 \mu\text{m}^2\text{s}^{-1}} \approx 0.001 \text{ s} \quad (5)$$

In terms of chemical reactivity, we can now ask how rapid an intracellular reaction must be in order to prevent this 'escape'. To a first approximation, the half-life of such a reaction should be in the range of this 'escape' time, and so we calculate the rate for a reaction with this half-life:

$$\text{rate} = \frac{\ln 2}{0.001 \text{ s}} = 6.93 \times 10^2 \text{ s}^{-1} \quad (6)$$

Assuming a second-order reaction between  $\cdot\text{NO}$  and a reactant R ( $\text{rate} = k[\cdot\text{NO}][\text{R}]$ ) and a very high intracellular R concentration (1 mM), the value for the rate constant  $k$  is given by:

$$k = \frac{6.93 \times 10^2 \text{ s}^{-1}}{10^{-3} \text{ M}} = 6.93 \times 10^5 \text{ M}^{-1} \text{ s}^{-1} \quad (7)$$

This is the rate constant for a quite rapid reaction. In addition, in order to provide continual inhibition of  $\cdot\text{NO}$  escape the reactant R must be continually maintained at this high concentration. Experimental support for the general concept that  $\cdot\text{NO}$  will rapidly escape a cell producing it is provided by the observation that coincubation of  $\cdot\text{NO}$ -producing isolated rat hepatocytes with intact erythrocytes eliminates the reaction of  $\cdot\text{NO}$  with targets within the  $\cdot\text{NO}$ -producing hepatocyte; it can be shown from first principles that the only explanation for this effect is if, on average, any individual  $\cdot\text{NO}$  molecule that acts within an  $\cdot\text{NO}$ -producing cell had at some time previously existed in the volume outside the cell.<sup>268,269</sup> Similar conclusions have recently been reported for formation of intracellular nitrosothiol.<sup>270</sup> In vivo, different cell types produce different reactive oxygen and nitrogen species. Spatially, this means that the appearance (flux) of these reactive species at any point location will be determined by the distance from this point to the cells producing these species. Thus, the precise chemistry that occurs at different locations can be very different, especially when dealing with highly interactive networks of interreacting species.

## 12 NITRIC OXIDE IN PATHOPHYSIOLOGY

Without doubt, the action of  $\cdot\text{NO}$  that has provided the single most attention in human disease is its role in penile erection,<sup>271</sup> thus providing the mechanistic basis for the most widely prescribed oral agent in medicine, Viagra (Sildenafil).<sup>272</sup> Production of  $\cdot\text{NO}$  by the corpus cavernosum results in relaxation of the vessels and engorgement of the organ with blood and consequent erection. The dilating action of  $\cdot\text{NO}$  lies at the beginnings of the realization of its biological actions and its clinical applications, since the use of nitrovasodilators to attenuate a variety of cardiovascular problems is nearly 140 years old.<sup>141</sup>

Abnormal production of  $\cdot\text{NO}$ , either too much or too little, has been linked to a remarkable number of clinically

important conditions. In two important early papers, it was shown by Kilbourn and Lodato that excessive  $\cdot\text{NO}$  contributes to the serious and life-threatening hypotension (loss of blood pressure) that occurs during systemic bacterial infection (sepsis).<sup>273,274</sup> Prior to these studies it had been demonstrated that severe hypotension accompanying sepsis is a result of the stimulation of lymphocytes and macrophages by bacterial products (most notably endotoxin), which results in massive production of circulating cytokines.<sup>275</sup> Indeed, injection of two cytokines (TNF and IL-1), in particular, in animals and humans produces many symptoms that are identical to septic shock, including hypotension, and administration of neutralizing antibodies or antagonists to these cytokines is capable of marked attenuation in the hypotensive response to injection of bacterial products. Kilbourn and Lodato showed that a similar protective response occurs against TNF or endotoxin injection in dogs when NMMA is administered to inhibit  $\cdot\text{NO}$  formation and this restoration in blood pressure is reversed (blood pressure again decreases) when L-arginine is subsequently injected.<sup>273,274</sup> The effect of NMMA is attributable to its prevention of  $\cdot\text{NO}$  formation by NOS and its reversal by excess substrate (L-arginine) is a classic example of competitive enzyme inhibition (Figure 2).

Some 600 000 patients annually are stricken with septic shock, with an estimated in-hospital mortality rate of 18%.<sup>276</sup> In humans, the importance of  $\cdot\text{NO}$  in maintaining normal vascular tone (blood pressure) was originally demonstrated by Vallance *et al.*,<sup>277</sup> and several early reports demonstrated restoration of near normal blood pressure in humans with sepsis, including one report where it appears to have saved a life.<sup>278</sup> In addition, it has been shown that septic patients have high circulating  $\text{NO}_3^-$  levels<sup>279</sup> (indicating excess  $\cdot\text{NO}$  formation). In the only large-scale clinical trial of the effects of NOS inhibitors on septic shock, NMMA was tested on a total of 797 patients<sup>280</sup> and, in spite of initial trials indicating beneficial effects,<sup>281</sup> patients administered NMMA exhibited increased mortality. Unfortunately, this has been a severe setback for further studies of the use of NOS inhibitors for this dread affliction, and investigators have been disappointed that this study using such a nonselective NOS inhibitor was pursued; as has been pointed out,<sup>282</sup> it is still quite possible that a new generation of iNOS-selective inhibitors could provide beneficial results.

A central paradigm in the field is that  $\cdot\text{NO}$  is 'Janus-faced'<sup>1</sup> in its roles in pathophysiology, exhibiting protective actions under some conditions and damaging effects in others. The possible mechanistic explanations for this paradoxical result can be viewed from two perspectives, cellular/tissue and molecular. In terms of cellular/tissue actions, one of the most important biological actions of  $\cdot\text{NO}$  is its potent inhibition of vascular coagulation and aggregation, which was reported more than 20 years ago.<sup>283</sup> This is a very important biological effect that will be protective in the many disorders involving aggregation and adhesion of blood cells, which interrupts the

free flow of blood and results in sites of vascular plugging and local inflammation.<sup>284</sup> Additional salutatory effects of  $\cdot\text{NO}$  in the vascular system are the inhibition of smooth muscle cell proliferation (thus attenuating disorders such as restenosis) and also promotion of angiogenesis (the growth of new blood vessels).<sup>284</sup> This latter action is an excellent illustration of the 'Janus-faced' roles of  $\cdot\text{NO}$ , where new blood vessel formation is beneficial for wound healing but  $\cdot\text{NO}$  has been implicated in the formation of new vessels to supply blood to tumors.<sup>285</sup>

The most commonly cited mechanistic explanation for the paradoxical roles of  $\cdot\text{NO}$  in cell and organ injury involves the interaction of  $\cdot\text{NO}$  with reactive oxygen species (ROS). The complexity of these reactions, many of which are mentioned above, leaves ample room to interpret results in terms of 'good' versus 'bad' by emphasizing one or another collection of reactions. Central to ROS biological actions is the metal-catalyzed Haber-Weiss reaction:<sup>286,287</sup>

According to this mechanism, it is actually the highly toxic and reactive hydroxyl radical ( $\cdot\text{OH}$ ) that causes most damage, produced by the interaction of  $\cdot\text{O}_2^-$ ,  $\text{H}_2\text{O}_2$ , and iron. The reaction that actually produces  $\cdot\text{OH}$  (the Fenton reaction) is the reduction of  $\text{H}_2\text{O}_2$  by  $\text{Fe}^{2+}$ . The function of  $\cdot\text{O}_2^-$  is twofold, both as a reductant for  $\text{Fe}^{3+}$  and also because it is a source for  $\text{H}_2\text{O}_2$ , either enzymatically (SOD) or by spontaneous dismutation. Although there is disagreement about how literally this scheme should be taken, it is a good paradigm within which to discuss  $\cdot\text{NO}$ /ROS interactions.

It is well-established that a major response to septic stimuli in general is the activation (primarily by cytokines and bacterial products, conditions that as described above also can induce  $\cdot\text{NO}$  synthesis) of phagocytic cells (neutrophils, macrophages) to produce ROS, through the respiratory burst mechanism;<sup>288,289</sup> this is a major immune mechanism for combating infectious agents but also can be damaging to the host.

In terms of potential chemical interactions, the effects of  $\cdot\text{NO}$  on ROS-induced injury are multiple, and some effects can be classified as 'prooxidant' and others may be classified as 'antioxidant'; still others can be classified as both. In terms of the metal-catalyzed Haber-Weiss reaction, there are two primary effects of  $\cdot\text{NO}$ . The binding of  $\cdot\text{NO}$  to metal ions will prevent the Fenton reaction and thus results in an antioxidant action.<sup>290–292</sup> Another important antioxidant action of  $\cdot\text{NO}$  (and its oxidized product  $\cdot\text{NO}_2$ ) is its reaction with lipid radicals, thus resulting in radical chain termination.<sup>23</sup>

One of the first pieces of evidence supporting the identification of EDRF as  $\cdot\text{NO}$  was the demonstration that

$\cdot\text{O}_2^-$  reacts rapidly with EDRF.<sup>293</sup> Early work suggested that  $\cdot\text{NO}$  could be protective against oxidative injury by reacting with, and thus scavenging, ROS.<sup>294</sup> However, in a landmark paper in 1990, Beckman *et al.*<sup>295</sup> brought attention to the fact that the product of the  $\cdot\text{NO}/\cdot\text{O}_2^-$  reaction, peroxynitrite, possesses highly oxidizing properties, thus,  $\cdot\text{NO}$  effectively converts a rather mild oxidant ( $\cdot\text{O}_2^-$ ) into a strong oxidant ( $\text{ONOO}^-$ ). This concept has become a central paradigm for interpretation of all prooxidant effects of  $\cdot\text{NO}$ , although its validity has been questioned.<sup>296</sup> In particular, since the rate of reaction of superoxide with  $\cdot\text{NO}$  is similar in magnitude to the rate of reaction with SOD, appreciable  $\text{ONOO}^-$  formation will occur only at locations where the  $\cdot\text{NO}$  concentration is greater than SOD concentration. The concentration of SOD inside most cells is quite appreciable (in the micromolar range) and so relatively high  $\cdot\text{NO}$  concentration would be required. This may be less of a problem extracellularly, where SOD levels are lower and also where appreciable superoxide is formed from phagocytic cells.<sup>297</sup> Nevertheless, in at least one case (motor neuron death in a model of amyotrophic lateral sclerosis, Lou Gehrig's disease) there is good evidence that intracellular peroxynitrite formation from  $\cdot\text{NO}$  and  $\cdot\text{O}_2^-$  is responsible for toxic effects.<sup>298</sup>

The major 'curse' of working with short-lived species such as radicals and oxidants is the dearth of methods to unambiguously demonstrate their existence and actions in situ (i.e. biologically). This has been especially true for peroxynitrite. In 1994 Beckman *et al.* introduced the use of antibodies directed to protein nitrotyrosines as an immunohistochemical method.<sup>299</sup> This was a very exciting development because at the time it was believed that this was a specific marker for peroxynitrite, based on the demonstration of nitrotyrosine formation from  $\text{ONOO}^-$ .<sup>300</sup> This has been followed by a deluge of papers using this method to demonstrate nitrotyrosine formation in a vast array of inflammatory disease states, thus inferring the presence of peroxynitrite in vivo. Unfortunately, it is now known that nitrotyrosine can be formed from a variety of mechanisms, involving principally metals (including peroxidases) in the presence of nitrite and  $\text{H}_2\text{O}_2$ .<sup>80,81</sup> The mechanistic link between these various conditions is the formation of  $\cdot\text{NO}_2$ , which combines with tyrosyl radical (formed from a number of possible oxidants) to form nitrotyrosine.<sup>301</sup>

In summary, in terms of chemistry the interactions of  $\cdot\text{NO}$  with ROS are many and complex.<sup>38</sup> The general paradigm that has emerged is that at low levels  $\cdot\text{NO}$  exerts beneficial effects, through several mechanisms including cellular signaling (e.g. inhibition of vascular aggregation and adhesion, vasodilation) and radical chain termination. At higher levels, and especially in the context of increased ROS (specifically,  $\cdot\text{O}_2^-$ ) formation,  $\cdot\text{NO}$  can greatly contribute to cellular injury. The chemical bases and understanding for this paradigm (if indeed accurate) in terms of reaction patterns of the network of reactive oxygen and nitrogen chemistry are largely unexplored.

### 13 NOVEL BIOLOGICAL ROLES OF •NO

Researchers in many previously unrelated fields of biology have recently become united by the discovery that •NO plays important roles in their systems. The typical experimental tools used in these numerous studies are the modulation of the observed biological effects by the addition of agents that attenuate (NMMA, hemoglobin, •O<sub>2</sub><sup>-</sup>) or potentiate (•NO donors, L-arginine) •NO production, as well as the correlation of •NO formation (NO<sub>2</sub><sup>-</sup>, NO<sub>3</sub><sup>-</sup> appearance) with the biological phenomenon of interest. In addition, it is possible to identify specific cells that are exceptionally rich in NOS and thus correlate the specific sites of •NO production with microanatomical function. In this last section, we briefly describe a few of these novel findings.

The endogenous production of •NO appears to be a phylogenetically widespread phenomenon. The initial reports of endogenous •NO in nonmammalian systems involved birds<sup>302</sup> and invertebrates.<sup>303</sup> It has also been shown that certain blood-sucking insects produce •NO in their salivary glands, and that it is delivered to the blood stream of its victims as a complex to a ferric iron-containing protein named nitrophorin (*see Iron Porphyrin Chemistry*).<sup>304,305</sup> Since •NO binds relatively poorly to Fe<sup>3+</sup> (compared to Fe<sup>2+</sup>),<sup>207</sup> the •NO dissociates and induces vascular dilation at the site of the bite. •NO is also involved in the mechanism of control of firefly flashing<sup>306</sup> as well as in other insects (including *Drosophila*) where it appears to perform a variety of signaling and immune roles,<sup>307</sup> as well as in plants where in fact the first enzymatic formation of •NO was reported.<sup>100,101</sup> •NO also plays a biological role in unicellular organisms, including protozoa; one clinically important aspect is that many pathogenic organisms produce •NO for unknown reasons.<sup>308</sup> •NO has been known for many years to be a component of the biological nitrogen cycle, being produced by bacteria during denitrification (*see Copper Enzymes in Denitrification*).<sup>309</sup> However, its role as a messenger in these bacteria is only now being appreciated.<sup>310</sup> Remarkably, *C. botulinum* has recently been shown to possess an •NO sensor that detects •NO down to the femtomolar range.<sup>311</sup> As described above, this organism, which produces the most toxic substance known to humans (the botulinum toxin), is extremely sensitive to nitrite and this sensitivity has been proposed to involve •NO.<sup>222</sup>

Undoubtedly other novel roles for •NO in biology will be discovered; its chemical properties are indeed unique and Nature will always find ways to exploit any chemical opportunity.

## 1 INTRODUCTION

Together with the transition metal carbides and borides, the transition metal nitrides belong to a family of materials that features an unusual combination of outstanding properties, among which are exceptional hardness, high melting point, metallic luster with sometimes vivid colors, and simple metallic structures combined with excellent electrical and thermal conductivities. This combination of these properties has attracted considerable attention and has resulted in numerous technical applications.<sup>1–4</sup> Lengauer<sup>5</sup> has recently compiled several features of transition metal nitrides and carbonitrides. Many of the nitride phases closely resemble metallic alloys, with broad ranges of homogeneity, particularly if the structure of the metallic host lattice is one of the types encountered in typical metals. They often form solid solutions with structurally related compounds such as other transition metal nitrides or carbides and are easily wetted by liquid metals of the iron group.

The chemical stability of transition nitrides is considerable; they are not readily attacked by dilute acids except by oxidizing acids and hydrofluoric acid or alkaline solutions. The thermal stability is determined by their free energies of formation; the stability decreases with increasing group number. While TiN, ZrN, and HfN can be melted without decomposition at ambient pressure, the nitrides of the other groups decompose by liberating nitrogen before melting points are reached.

Table 1 gives a brief survey of the most important properties of the well-characterized binary transition metal nitrides. It should, however, be emphasized that practically all properties

are significantly influenced by the nitrogen to metal ratio (Section 6) and by impurities.

## 2 STRUCTURE AND BONDING

### 2.1 Structures: General Features

Transition metal nitrides together with the structurally closely related transition metal carbides belong to the family of ‘interstitial compounds’ or alloys. The common features of this class of materials are the very simple metallic structures with the smaller nitrogen atoms in the interstitial voids of the frequently dense-packed host lattice. The simple conceptual Hägg model in which the basically metallic character of the host metal is thought to be only modified by insertion of nonmetal atoms into the voids had to be substantially restructured in the light of modern bonding theories in order to account for the strong binding energies observed between transition metal atoms and nonmetal atoms. Nevertheless, the rather approximate interstitial alloy concept has proved helpful for gaining insight into the basic principles governing the structures of interstitial alloys and compounds.

Because of structural similarities, transition metal nitrides usually form solid solutions with transition metal carbides. However, there are important differences, possibly owing to the different bonding character of nitrogen as compared to that of carbon. Transition metal carbides and nitrides generally have face-centered cubic (fcc) or hexagonal close-packed (hcp) metal lattices with nonmetal atoms more or less randomly distributed on the interstitial sites; deviations from this simple concept are much more frequently encountered with nitrides. If the immediate neighborhood of the nonmetal X (X = C, N) is considered, one can define the structural elements of interstitial alloys.<sup>6</sup> In the group 4 and 5 transition metals, the common structural element of the nitrides and carbides is the  $T_6X$  octahedron. With increasing radius ratio  $r_X/r_T$ , the trigonal prismatic group  $T_6X$  is favored over the octahedral group. Therefore, the transition metal carbides of groups 6–9 feature trigonal prismatic  $T_6X$  elements in different crystallographic arrangements. In transition metal nitrides, a third structural element is occasionally observed, particularly in group 5 compounds, consisting of  $T_5X$  square pyramids. These prevail even in the complex nitrides, such as the Z-phases NbCrN, TaCrN, NbMoN, and TaMoN with the filled  $\Theta$ -CuTi-type structure. With this square pyramid, which has lower symmetry than an octahedron, such nitrides have more complicated structures (Section 5.2) than the corresponding carbides.

Because of the formation of structural elements other than  $T_6N$  octahedra, the fcc structure of  $\delta$ -nitrides is destabilized increasingly with increasing group number and, within a group, with increasing periodic number. For example, the nitrides of group 4,  $\delta$ -TiN<sub>1-x</sub>,  $\delta$ -ZrN<sub>1-x</sub> and

$\delta$ -HfN<sub>1-x</sub> crystallize in the sodium chloride structure. No low-temperature modifications of these stoichiometric nitrides are known. In group 5, all three metals form stoichiometric fcc nitrides, too, but  $\delta$ -VN<sub>1.00</sub> transforms below 205 K into a tetragonal modification,<sup>7</sup>  $\delta$ -NbN<sub>1.00</sub> below around 1320 °C into hexagonal  $\eta$ -NbN,<sup>8</sup> and  $\delta$ -Ta<sub>1.00</sub> below around 1920 °C congruently into hexagonal  $\varepsilon$ -Ta<sub>1.00</sub>.<sup>9</sup> In group 6, these fcc nitrides are increasingly less stable: fcc CrN is nearly a line compound at low temperature with a reduced thermochemical stability and transforms below approximately 280 K into a tetragonal antiferromagnetic compound,<sup>10</sup> and fcc  $\gamma$ -MoN<sub>1-x</sub> apparently does not even occur with a nitrogen content approaching the ideal composition MoN<sub>1.00</sub> (except perhaps at very high pressures) but rather in the vicinity of MoN<sub>0.50</sub>. Face-centered cubic MoN<sub>0.50</sub> also transforms into a tetragonal modification with an ordered arrangement of nitrogen atoms in the interstitial sites. This tendency proceeds further in the Mn-N and Fe-N systems, where ferromagnetic fcc phases with the stoichiometry T<sub>4</sub>N are observed with an ordered arrangement of N atoms.<sup>11</sup> Ordered manganese nitride phases with respect to the arrangements of nitrogen and a concurrent tetragonal distortion of the metal host lattice are found. An fcc MnN<sub>1-x</sub> was recently prepared by high-rate reactive sputtering.<sup>12</sup>

An extensive compilation of nitride phases is contained in Pearson's handbook<sup>13</sup> and in the ASM binary phase diagram compilation.<sup>11</sup>

The different stacking of close-packed metal layers can be described by the Jagodzinski–Wyckoff notation, where close-packed stacking ABC,ABC, . . . is designated as 'c' and hexagonal close-packed stacking AB,AB, . . . is designated as 'h'. Figure 1 shows these structures and lists several metal nitride and carbide phases that can be described with this formalism.

## 2.2 Bonding

The bonding in transition metal carbides and nitrides can be described as a mixture of metallic, covalent, and ionic components.

The metallic character is immediately noticed in the high electrical conductivities of these compounds. The bonding mechanism has been described extensively by a variety of approaches for calculating the density of states (DOS) and hence the electron density in fcc transition metal nitrides, carbides and oxides.<sup>14</sup> In the DOS of these compounds, there is a minimum at a valence electron concentration (VEC) of eight that corresponds to the stoichiometric composition of group 4 carbides TiC, ZrC and HfC. Figure 2 compares the decomposed and the total DOS of TiN and TiC<sup>15</sup> with respect to the s, p, and d bands. At low energies of <0 Ryd the s band is characterized by a large contribution of the nonmetal 2s state. Above 0 Ryd the p band follows and there is a significant contribution of d states to this band, too. At higher energies, the d band composed of d states follows with the Fermi energy E<sub>F</sub>

**Figure 1** Close-packed structure types observed for various transition metal nitrides. Large circles designate metal atoms, small circles designate nitrogen atoms. In h sequences, only 50% of the interstices can be occupied. The following transition metal nitrides crystallize in these structures: h:  $\beta$ -V<sub>2</sub>N,  $\beta$ -Nb<sub>2</sub>N,  $\beta$ -Ta<sub>2</sub>N,  $\varepsilon$ -Cr<sub>2</sub>N,  $\zeta$ -Mn<sub>2</sub>N,  $\varepsilon$ -Fe<sub>2</sub>N; c:  $\delta$ -TiN<sub>1-x</sub>,  $\delta$ -ZrN<sub>1-x</sub>,  $\delta$ -HfN<sub>1-x</sub>,  $\delta$ -VN<sub>1-x</sub>,  $\delta$ -NbN<sub>1-x</sub>,  $\delta$ -Ta<sub>1-x</sub>,  $\gamma$ -MoN<sub>1-x</sub>; (hc)<sub>2</sub>: ScNbN, ScTa<sub>2</sub>N, Mn<sub>3</sub>TaN<sub>4-x</sub>; (hc)<sub>2</sub> with metal and nonmetal sites exchanged:  $\eta$ -NbN,  $\eta$ -Ta<sub>2</sub>N; (hcc)<sub>3</sub>:  $\eta$ -Ti<sub>3</sub>N<sub>2-x</sub>,  $\eta$ -Hf<sub>3</sub>N<sub>2-x</sub>; (hcc)<sub>3</sub>:  $\zeta$ -Ti<sub>4</sub>N<sub>3-x</sub>,  $\zeta$ -Hf<sub>4</sub>N<sub>3-x</sub>

located well within this band. The DOS at E<sub>F</sub> is higher for TiN than for TiC, consistent with the observed superconducting properties (TiN, T<sub>C</sub> = 5.4 K; TiC, T<sub>C</sub> < 1.2 K) and room-temperature electrical conductivities (Section 6.3).

An illustrative picture of covalent bonding in these compounds can be drawn in the molecular orbital (MO) scheme<sup>16</sup> where atomic orbitals of atoms are combined to form bonding and antibonding states. Figure 3 shows a schematic drawing of these bonds between metal d and nonmetal p orbitals in the (100) plane of the fcc structure, which can be decomposed into two different bonding symmetries, t<sub>2g</sub> and e<sub>g</sub>. It can be shown that the calculated electron densities in this plane reflect the change of e<sub>g</sub> bonding symmetry in TiC to t<sub>2g</sub> bonding symmetry in TiN. Thus the exchange in bonding strength from a strong Ti–C interaction in TiC toward a more pronounced Ti–Ti interaction in TiN is to be expected.

The ionic contribution to the binding mechanism of transition metal nitrides and carbides can be estimated from

**Figure 2** Density of states (DOS) for TiC and TiN. (Ref. 15. Reproduced by kind permission of Kluwer Academic Publishers)

**Figure 3** Bonding schemes: (a) of different symmetries in the (100) plane and calculated electron densities and (b) of TiN and TiC showing the change around Ti from  $e_g$  symmetry TiC to  $t_{2g}$  bonding symmetry in TiN. (Ref. 16. Reproduced by permission of Wiley, Inc)

the charge transfer from the metal atom to the nonmetal atom. It is about half an electron per atom, which contributes to the electrostatic interaction of metal and nonmetal.

The bonding of 4d transition metal nitrides and carbides can be treated in a very similar way; the nonmetal contribution to the electron density is about the same, whereby the contribution from 4d electrons causes a more spatial extension

of electron density than in 3d compounds. In 5d transition metal nitrides and carbides, relativistic effects due to the heavy cores have to be taken into account.

### 3 PREPARATION

Transition metal nitrides can be prepared by allowing the metal or the metal hydride in powdered or compact form to react with molecular or atomic nitrogen or flowing ammonia:

The pressure of molecular nitrogen at a given temperature that is necessary to obtain a specific nitride phase is defined by the nitrogen potential (partial free energy of nitrogen) of the nitride. In flowing ammonia, very high nitrogen potentials can be maintained as long as the thermal decomposition of ammonia into  $\text{N}_2 + 3\text{H}_2$  can be minimized.

The formation of nitrides from oxides is performed in the presence of carbon as a reducing agent, according to the overall reaction

This reaction usually proceeds over several intermediate products and the resulting nitride may contain oxygen and carbon.

For the preparation of nitrides from metal powders, the exothermic heat of formation can be utilized in the self-sustaining high-temperature synthesis (SHS) process. If the reaction is exothermic enough, that is, if the heat generated is sufficient to reach the reaction temperature, then the starting material is converted to the nitride and the heat is dissipated. For the preparation of large crystals, zone-annealing techniques have been developed.<sup>17</sup> Similar to the zone-melting process, a heated zone is passed along a rod in a nitrogen atmosphere. The starting materials are either solid-state sintered nitride powders or metal powders pressed into rods. The applied temperatures must be very high (ca. 3000 °C) in order to overcome the low diffusivity of nitrogen in nitrides, but they must not exceed the melting temperatures of the compounds in order to avoid incongruent melting and decomposition. Crystals on the order of 1 cm<sup>3</sup> have been produced by this technique. While they still may show some concentration gradients, they are suitable for solid-state investigations such as neutron diffractometry.

A great variety of methods have been applied to the preparation of nitride layers. These can be divided into three main groups (Section 7.1 gives more details).

- Chemical vapor deposition (CVD) – a volatile transition metal compound such as a chloride is reacted in the gas phase with ammonia, nitrogen/hydrogen or ammonia/hydrogen/nitrogen mixtures. The high-melting nitride that forms as a reaction product in the gas phase nucleates on any solids present, for example, hard metals, and forms compact strongly adhering layers at temperatures around 1000 °C.
- Physical vapor deposition (PVD) – the transition metal is evaporated by electron beam or plasma heating or sputtered by glow discharge and reacted with low-pressure nitrogen (typically in the range of  $10^{-4}$  mbar). Numerous modifications of PVD methods have been developed. The nitride layers that are deposited on the substrate often have high lattice defect concentrations and hence exhibit significant deviations from generally known bulk values (lattice parameters, hardness, composition, etc.).
- Surface nitridation is widely used for surface hardening and can be achieved by subjecting the material surface to the action of ammonia, molecular or atomic nitrogen, or nitrogen ions. Case-hardening techniques also make use of cyanide salt baths to form nitrides or carbonitrides on material surfaces. Reactive plasma techniques and high-pressure techniques have been developed to keep the workpiece temperature low and to avoid thermally induced changes in the workpiece. Laser irradiation together with an  $N_2$  jet directed on the heated spot is employed for locally limited heating of the sample. This nitridation method is applicable to titanium alloys (e.g. Ti6Al4V) used to create wear- and corrosion-resistant layers on steam turbine blades for protection against droplets having supersonic velocity.

## 4 CHARACTERIZATION

### 4.1 Chemical Analysis

Several procedures have been applied for the analysis of nitrogen and impurities such as oxygen and carbides in nitrides.

- Combustion analysis<sup>18</sup> according to the Dumas method – the sample is heated at temperatures of up to 1200 °C in oxygen and/or with oxidizing agents such as  $V_2O_5$ , CuO, or  $Cu_2O$ . The evolved  $N_2$  is either measured volumetrically in an azotometer or via a gas chromatograph<sup>19</sup> equipped with a thermoconductivity detector. With the latter equipment, C and H can also be determined simultaneously via the combustion products  $CO_2$  and  $H_2O$ . The accuracy of

the method is better than 1 rel %N for finely powdered samples if combustion can be completed within a rather short time span.

- Carrier gas hot extraction – the sample is heated to more than 2000 °C in the presence of carbon and an auxiliary bath of metal such as platinum and in a stream of a carrier gas such as He. Nitrogen is liberated as  $N_2$  and is usually measured in a thermoconductivity cell. Oxygen combines with C to give CO and can thus be analyzed. Because of the high temperatures involved, the method is suitable for powder samples with larger grain size or even for small solid pieces. The accuracy of the method is on the order of 1–2 rel %N.
- Kjeldahl analysis – this involves the dissolution of nitrides in acids whereby the nitrogen is converted into ammonium ions. The dissolution process may be time consuming since some nitrides, such as  $\delta\text{-TiN}_{1-x}$ , are chemically very stable against acids and must be dissolved using severe conditions such as by the action of hydrofluoric acid in Polytetrafluorethylene (PTFE) containers at 100–200 °C. It is doubtful whether all of the nitrogen can be converted into  $NH_4^+$  so systematic errors may arise.

### 4.2 Physical Analysis

Among the microphysical methods used for the analysis of nitrogen in nitrides, e.g. electron probe microanalysis (EPMA), Auger electron spectroscopy (AES), ultraviolet X-ray spectroscopy (UPS) and X-ray spectroscopy (XPS), secondary ion- or neutral mass spectrometry (SIMS, SNMS) and Rutherford backscattering (RBS), EPMA is considered to have the highest reproducibility and accuracy, provided that the lateral resolution of only a few microns is sufficient. The main problem in EPMA is the rather low energy of  $N_{K\alpha}$  radiation. Even with windowless detector systems, a high background-to-peak ratio together with low net intensities are the result.<sup>20</sup> High-accuracy EPMA requires external or internal standardization<sup>21</sup> together with a wavelength-dispersive spectrometer equipped with high-quality crystals (e.g. W-Si multilayer or lead stearate crystals). For standardization, diffusion couples have been used in which diffusion layers are broadened.<sup>22–24</sup> Such samples can even be prepared in single-phase form upon increase of diffusion time so that the gross chemical composition is the same as the phase composition, a necessary prerequisite for application of different analyzing techniques and for true standardization.<sup>25</sup> By such a method, single-phase standards of TaN,<sup>26</sup> CrN,<sup>27</sup> and  $\zeta\text{-Hf}_3\text{N}_{3-x}$ <sup>28,29</sup> have been prepared. These phases have a very narrow homogeneity range at least at a certain temperature.

Neutron activation analysis (NAA) making use of the nuclear reaction  $^{14}\text{N}(n,2n)^{13}\text{N}$  can be applied for bulk determination of nitrogen.

## 5 THERMODYNAMICS

### 5.1 Nitrogen Partial Pressure

The nitrogen partial pressure of the transition metal nitrides is a function of temperature and increases substantially with

increasing group number. This is reflected in the Richardson diagram shown in Figure 4. The lower (the more negative) the free energy of formation the lower is the equilibrium nitrogen pressure of the nitride. Group 4 nitrides can easily be obtained by nitridation of the metals with molecular nitrogen under low pressures even at high temperatures, whereas for the group

**Figure 4** Richardson diagram of various transition metal mononitrides (together with other nitrides) giving the free energy of formation as a function of temperature. (Ref. 4. Reproduced by permission of Wiley VCH)

**Figure 5** Phase diagram of the Ti–N system. (Reprinted from Ref. 31. © 1991, with permission from Elsevier)

5 nitrides the nitrogen pressure must already exceed normal pressure at temperatures above 1400 °C, and even higher pressures or more energetic nitriding conditions must prevail for the preparation of group 6 nitrides.

The nitrogen pressure determines the composition of the nitride if equilibrium is attained. Thermochemical models have been established that correctly predict pressure-temperature-composition (p-T-x) relationships for nitride phases.<sup>30</sup>

Nitride phases with a nonmetal to metal ratio greater than one have been obtained with high-pressure nitrogen or at high nitrogen potentials, such as those prevailing in flowing ammonia or ionic nitrogen atmospheres. Either an extension of the mononitride phase field to compositions  $N/T > 1$  has been observed such as in the Nb–N, Hf–N, and Ta–N systems, or distinct nitride phases are observed such as in the Zr–N, Nb–N, and Ta–N systems.

Ion implantation techniques can lead to nitrides having extremely high nitrogen to metal ratio such as  $TiN_{1.5}$  but these phases are probably metastable.

## 5.2 Phase Equilibria and Structural Features

Several of the transition metal-nitrogen systems are not yet fully established. This is especially the case for some of the metals in groups 6–9, probably because of the lower technical relevance of the nitrides and the high nitrogen pressures needed for equilibrium investigations.

### 5.2.1 The Ti–N System

The Ti–N system<sup>31</sup> features a high solubility of nitrogen in  $\alpha$ -Ti, the three subnitride phases  $\eta$ - $Ti_3N_{2-x}$ ,  $\zeta$ - $Ti_4N_{3-x}$  and  $\epsilon$ - $Ti_2N$ , and the fcc phase  $\delta$ - $TiN_{1-x}$  with the sodium chloride structure.  $\eta$ - $Ti_3N_{2-x}$  and  $\zeta$ - $Ti_4N_{3-x}$  have been found to be isostructural with the hafnium subnitride phases and are characterized by metal atom layers comprising cubic- and hexagonal stacking sequences (Figure 1). Figure 5 shows the phase diagram of the Ti–N system.

In  $\delta$ - $TiN_{0.50}$ , the random distribution of nitrogen atoms undergoes an ordering process<sup>32</sup> below about 880 °C with a concurrent tetragonal distortion of the metal lattice.<sup>33</sup> The so-formed  $\delta'$ - $TiN_{0.5}$  phase is only formed from  $\delta$ - $TiN_{1-x}$  by lattice distortion and is not an equilibrium phase (e.g. it is not formed in isothermal diffusion couples in the form of a phase band).

### 5.2.2 The Zr–N System

If the solid solution of nitrogen in Zr,  $\alpha$ -Zr(N), which exists up to a composition ' $Zr_2N$ ', is not considered as a nitride phase, the Zr–N system is characterized by the presence of only one nitride phase,  $\delta$ -ZrN<sub>1-x</sub> up to a composition of approximately  $[N]/[Zr] = 1$ . It should be mentioned that none of the subnitride phases that exist in the neighboring systems Ti–N and Hf–N occur here. In Massalski's compilation<sup>11</sup>

**Figure 6** Phase diagrams of group 4 transition metal-nitrogen systems. (a) Zr–N. (Ref. 11. Reproduced by permission of Materials Information Society/ASM International), (b) Hf–N. (Reprinted from Ref. 28. © 1991, with permission from Elsevier)

(Figure 6), the  $\text{Zr}_3\text{N}_4$  phase<sup>34</sup> that can be obtained by reacting  $\text{ZrCl}_4$  with  $\text{NH}_3$  has not been included.

### 5.2.3 The Hf–N System

Besides the fcc  $\delta\text{-HfN}_{1-x}$ , the Hf–N system contains two subnitride phases,<sup>35</sup>  $\eta\text{-Hf}_3\text{N}_{2-x}$  and  $\zeta\text{-Hf}_4\text{N}_{3-x}$ . Only a few phase equilibria studies have been performed for this system. Figure 6 shows the compiled phase diagram together with results from diffusion couples.<sup>28,29</sup> The homogeneity ranges of the subnitride phase could be established. The decomposition temperatures of these phases need to be reinvestigated.

### 5.2.4 The V–N System

In the vanadium–nitrogen system, the phases  $\beta\text{-V}_2\text{N}$  and  $\delta\text{-VN}_{1-x}$  have cph and fcc structures, respectively. Carlsson *et al.*<sup>36</sup> have reviewed the V–N system and reinvestigated the vanadium-rich portion. Compiled data and results of a phase diagram study based on diffusion couples<sup>37</sup> have been used to construct the phase diagram shown in Figure 7.

Stoichiometric VN undergoes a phase transition into a tetragonal phase below 205 K.<sup>7</sup> At a composition of around  $\text{VN}_{0.80}$ , a transition into a tetragonal phase occurs at 500 °C. Two different versions of the phase diagram at temperatures below 500 °C have been reported,<sup>39,40</sup> one with a eutectic and one with a peritectic phase reaction between tetragonal  $\text{VN}_{0.83}$  and  $\delta\text{-VN}_{1-x}$ .

### 5.2.5 The Nb–N System

Brauer *et al.*<sup>41,42</sup> made careful studies on p–T–x relationships in the Nb–N system. In recent years, the phase reactions in this system have been investigated by high-temperature X-ray diffraction as well as by use of diffusion couples.<sup>38,43,44</sup> The phase reactions could be assumed as established (Figure 7). Interestingly,  $\gamma\text{-Nb}_4\text{N}_{3-x}$  is formed by a martensitic transformation from  $\delta\text{-NbN}_{1-x}$ , hence an interface between  $\delta\text{-NbN}_{1-x}$  and  $\gamma\text{-Nb}_4\text{N}_{3-x}$  does not form in diffusion couples.<sup>38</sup>

Near the composition NbN, at least three phases have been observed. For  $\eta\text{-NbN}$ , two different structures have been proposed with respect to the nitrogen positions. It contains trigonal prismatic and octahedral  $\text{T}_6\text{N}$  structure elements and features a metal layer sequence AABB.  $\eta\text{-NbN}$  undergoes a phase transition at about 1320 °C (depending on the nitrogen pressure) into fcc  $\delta\text{-NbN}_{1-x}$  with a sodium chloride structure. Another phase,  $\delta'\text{-NbN}_{0.97}$  is most probably oxygen stabilized or occurs as metastable phase with phase transitions and is not included in the phase diagram. By reacting Nb powder with nitrogen under high pressure, the composition of the  $\delta\text{-NbN}_{1-x}$  phase can be extended beyond  $\text{N/Nb} = 1$ . At even higher nitrogen pressure, the phase  $\text{Nb}_5\text{N}_6$  can be prepared.  $\text{Nb}_5\text{N}_6$  is isotypic with  $\text{Ta}_5\text{N}_6$  and features  $\text{T}_5\text{N}$  square pyramids structural elements. These structural elements have not been observed in the analogous carbide systems and are probably linked to the higher electron concentration in nitrides.

### 5.2.6 The Ta–N System

The lower stability of the tantalum nitride phases as compared to the nitrides of the group 4 metals is reflected in the substantially higher equilibrium pressures (Figure 7).<sup>45</sup> In order to prepare the high-temperature fcc phase  $\delta\text{-TaN}_{1-x}$ , the nitrogen pressure must exceed 10 bar but can be stabilized at lower pressures and temperatures by minute amounts of carbon. It is the hardest known transition metal nitride phase. The  $\text{Ta}_2\text{N}$  phase belongs to the  $\varepsilon\text{-Fe}_2\text{N}$  type at low temperatures and undergoes an order-disorder transition to

**Figure 7** Phase diagram of group 5 transition metal-nitrogen systems. (a) V–N. (Ref. 37. Reproduced by permission of Materials Information Society/ASM International); (b) Nb–N. (Reprinted from Ref. 38. © 2000, with permission from Elsevier); and (c) Ta–N. (Reprinted from Ref. 38. © 2000, with permission from Elsevier)

an L/3 type between 1600 and 2000 °C. The often cited melting point of TaN of 2950 °C is probably incorrect and has to be attributed to Ta<sub>2</sub>N. TaN is expected to melt at

about 2800–3000 °C and nitrogen equilibrium pressures of 1–3 kbar. The θ-TaN phase with a WC-type structure is often observed in the reaction products of Ta powder with nitrogen or ammonia at temperatures below 1100 °C and is believed by Brauer *et al.*<sup>46</sup> to be a high-pressure phase that is metastable under normal conditions. ε-TaN has a structure not encountered in carbides, featuring an arrangement of Ta<sub>5</sub>N squared pyramids. There are three stoichiometric phases in the Ta–N system with decreasing metallic character. The one with the highest nitrogen content, red Ta<sub>3</sub>N<sub>5</sub> is nonmetallic and has been synthesized by the reaction of TaCl<sub>5</sub> with NH<sub>3</sub>. In this rhombohedral phase, the nitrogen atoms are situated in the centers of tetrahedra while the tantalum atoms are still sixfold coordinated by nitrogen atoms in the form of slightly distorted octahedra.

### 5.2.7 The Cr–N System

The Cr–N system is characterized by the nitride phases Cr<sub>2</sub>N<sub>1-x</sub> and CrN. The former has an appreciable homogeneity range. The arrangement of the metal atoms is cph and the nitrogen atoms are distributed in an ordered arrangement in the interstitial voids corresponding to the ε-Fe<sub>2</sub>N-type structure. CrN crystallizes in the sodium chloride type structure and its homogeneity range at low temperature is rather narrow whereas it is substantially broadened above about 1230 °C.

Cr<sub>2</sub>N<sub>1-x</sub> is readily dissolved by dilute acids, whereas CrN appears to withstand acid attack for prolonged periods. CrN is paramagnetic at room temperatures and undergoes a paramagnetic-antiferromagnetic first-order transition at temperatures between 276 and 286 K, depending on the composition.<sup>10</sup> The phase equilibria in the Cr–N system are strongly dependent on the nitrogen pressure. A phase diagram based on literature compilation and a study by diffusion couples is shown in Figure 8.<sup>27</sup>

### 5.2.8 The Mo–N and W–N Systems

In the Mo–N system (phase diagram<sup>47</sup> in Figure 8), three nitride phases have been reported. An fcc phase, originally named γ-Mo<sub>2</sub>N because of its composition around 33 at %N, should instead be written as δ-MoN<sub>1-x</sub> to be consistent with the notation for other fcc nitrides. Diffusion couple studies gave a homogeneity range at 1000 °C of 28.5–38.2 mol %N.<sup>48</sup> Since fcc-Mo<sub>2</sub>N<sub>1-x</sub> has been reported to exist at nitrogen contents above 33 at % and since it forms solid solutions with fcc δ-CrN, it can be assumed to be basically of the fcc δ-nitride type. This compound undergoes an ordering transition of the nitrogen atoms and a concurrent tetragonal distortion of the metal lattice into β-Mo<sub>2</sub>N between 400 and 850 °C, depending on the composition. A hexagonal phase, Mo<sub>2</sub>N, which would be expected by analogy with the other transition metal nitride systems, appears to be thermodynamically less stable than the cubic phase because in the ternary system Mo–C–N the

**Figure 8** Phase diagrams of group 6 transition metal-nitrogen systems. (a) Cr–N system. (Ref. 11. Reproduced by permission of Materials Information Society/ASM International December, with results from diffusion couples<sup>27</sup>), (b) Mo–N; isobar pressures are given in bar. (Ref. 47. Reproduced by kind permission of Springer Science & Business Media)

compositional range of the hexagonal solid solution  $\text{Mo}_2(\text{C},\text{N})$  extends from  $\text{Mo}_2\text{C}$  to approximately  $\text{Mo}_2(\text{C}_{0.35},\text{N}_{0.65})$ .<sup>49</sup>

Another phase,  $\delta\text{-MoN}$ , with a structure similar to that of WC, has been prepared by various methods including nitridation of Mo powder with flowing ammonia and reaction of  $\text{MoCl}_5$  with  $\text{NH}_3$ . It has been structurally characterized to have several types of ordered arrangements of nitrogen in the centers of trigonal prismatic structure elements.<sup>50</sup>

While at least 15 different nitride phases with compositions ranging between  $\text{W}_2\text{N}$  and  $\text{WN}_2$  have been reported, none of them appear to be very well characterized. As for the Mo–N system, an fcc nitride  $\text{WN}_{1-x}$  appears to exist since nitridation experiments<sup>51</sup> under pressure in the Mo–W–N system have shown that the fcc  $\text{MoN}_{1-x}$  phase is able to form extended solid solutions with the isotypic phase  $\text{WN}_{1-x}$ . The pressure

required to bring molecular nitrogen to reaction with tungsten powder at such temperatures, where kinetics are favourable, appears to be beyond the pressures available in standard laboratories. It is quite probable that another phase, WN with a WC-type structure, exists; it has at least been shown that nitrogen stabilizes the quaternary solid solution  $(\text{Mo},\text{W})(\text{C},\text{N})$  with a WC-type structure. Except for the solubility of nitrogen in bcc WN, no reliable data for this system are available.

#### 5.2.9 The Mn–N, Fe–N, Ni–N and Co–N Systems

The Mn–N system<sup>11</sup> bears some resemblance to the Cr and Fe nitride systems. The correspondence to the Cr–N system manifests itself by the existence of the  $\text{Mn}_2\text{N}_{1-x}$  phase with a cph arrangement on Mn atoms as well as two nearly cubic phases with compositions  $\eta\text{-Mn}_4\text{N}_3$  and  $\delta\text{-Mn}_6\text{N}_5$ .

Similarity to the Fe–N system is reflected by the extensive solid solubility of nitrogen, particularly in the fcc manganese (austenite) phase and the occurrence of a ferromagnetic  $\text{Mn}_4\text{N}$  phase. The nitrides with higher nitrogen contents,  $\eta\text{-Mn}_4\text{N}_3$  and  $\delta\text{-Mn}_6\text{N}_5$ , can only be prepared by the reaction of ammonia with manganese powder at rather low temperature, suggesting that the equilibrium pressures of nitrogen are very high even at moderate temperatures.  $\eta\text{-Mn}_4\text{N}_3$  resembles in its structure the ordered phases  $\text{Mn}_4\text{N}_3$  and  $\beta\text{-Mn}_2\text{N}$ , where ordering of the nitrogen atoms at the interstitial sites is accompanied by a tetragonal distortion of the cubic lattice. The  $\theta\text{-Mn}_6\text{N}_5$  phase comes very close to the stoichiometric composition  $\text{MnN}$  but still has a clearly visible tetragonality of the basically fcc lattice. CrN apparently stabilizes an fcc solid solution extending from CrN up to  $(\text{Cr}_{0.2}\text{Mn}_{0.8})\text{N}_{1-x}$  at 1000 °C and 800 bar  $\text{N}_2$ .<sup>52</sup>

The solubility of nitrogen in austenite ( $\gamma\text{-Fe}$ ) is much higher than that in  $\alpha\text{-Fe}$ , and in this respect nitrogen behaves similarly to carbon. Upon cooling of nitrogen-containing austenite, a structure develops that is similar to pearlite and is consequently called *nitrogen pearlite*. Unlike carbon, nitrogen forms an ordered  $\text{Fe}_4\text{N}$  phase that is ferromagnetic below 480–508 °C. At about 680°  $\text{Fe}_4\text{N}$  transforms into  $\varepsilon\text{-Fe}_2\text{N}_{1-x}$  and in that respect the close similarity to the Mn–N system becomes apparent. Besides  $\varepsilon\text{-Fe}_2\text{N}$  with an ordered arrangement of nitrogen atoms on the interstitial sites between the hexagonal arranged metal atoms, the  $\zeta\text{-Fe}_2\text{N}$  phase with a slightly higher nitrogen content and an orthorhombic distortion of the cph metal lattice has been reported. Figure 9 presents the Fe–N system with pressure isobars.<sup>53</sup>

Various iron nitrides and carbonitrides are formed during case hardening of steels and alloyed steels.<sup>54</sup> These iron nitrides are hard, highly wear resistant and usually do not lead to dimensional changes in the case-hardened items.

While there are no phase diagrams available for the Co–N and Ni–N systems, it can be supposed that they are similar to the Fe–N system but with even higher equilibrium pressures. Several phases have been prepared by the reaction of flowing ammonia with Co and Ni powder.

**Figure 9** Phase diagram of the Fe–N system: isotherm pressures are in bar; the region around the  $\zeta$ -Fe<sub>2</sub>N phase has been modified. (Ref. 53. Reproduced by permission of Royal Institute of Technology, Stockholm)

### 5.2.10 Ternary and Higher-order Nitride Systems

Binary transition metal nitrides can form ternary solid solutions with each other if they are isostructural and if their lattice parameters differ by no more than about 10–15%.  $\delta$ -VN<sub>1-x</sub> and  $\delta$ -ZrN<sub>1-x</sub> do not form extensive solid solutions with each other and the intersolubility of  $\delta$ -VN<sub>1-x</sub> and  $\delta$ -HfN<sub>1-x</sub> is not complete.

Ternary phases with structures different from those of the phases of the binary boundary systems are more the exception than the rule. Such phases have been reported in the systems Nb–Mo–N, Ta–Mo–N, Nb–Ta–N, Zr–V–N, Nb–Cr–N, and Ta–Cr–N. Information about ternary transition metal–nitrogen systems is often available for specific temperatures only.<sup>55</sup> This is even more the case for quaternary nitride systems, which play a role in the production of carbonitride cermets where quaternary compounds of the types (Ti,Mo)(C,N) and (Ti,W)(C,N) are of interest (see *Carbides: Transition Metal Solid-state Chemistry*), as well as in layer technology where titanium nitride-based coatings of the type Ti(C,B,N) are prepared by magnetron sputtering. Layers consisting of ternary compounds of the type (Ti,Al)N and (Ti,V)N also have favorable properties<sup>56</sup> with respect to abrasion resistance.

A further group of ternary nitrides are of the type R<sub>2</sub>Fe<sub>17</sub>N<sub>x</sub> where R is a rare earth element such as Sm, Ce or Nd, and x indicates the variable nitrogen content. These phases have been prepared, by nitridation at relatively low temperatures and up to 15 MPa N<sub>2</sub>, under which conditions the nitrogen content can reach  $x = 3$ . They are closely related to borides and carbides with the similar formula and have attracted considerable

interest for hard-magnetic applications.<sup>57</sup> It has been reported that these phases can reach compositions where  $x = 6$ , using a combination of hydrogen and nitrogen treatments.

Additional generally interesting phases from the crystal chemistry viewpoint are the H-phases,<sup>58</sup> for example, Ti<sub>2</sub>AlN, nitrogen perovskites, filled  $\beta$ -manganese-type phases, and Nowotny<sup>6</sup> phases.

## 6 PROPERTIES OF fcc TRANSITION METAL NITRIDES

For carbonitrides, (see *Carbides: Transition Metal Solid-state Chemistry*).

### 6.1 Melting Points

Melting points of various nitrides<sup>59</sup> have been measured under nitrogen pressures up to 300 bar. The nitrogen pressure has to be chosen in such a way as to be equal to the nitrogen equilibrium pressure of the nitride at its melting point. The melting point temperatures of the various nitrides can reach more than 3000 °C and can be read from the phase diagrams given in Section 5.2.

### 6.2 Color

Many mononitrides exhibit vivid colors of a bright metallic appearance that depends on the N/T ratio. Table 1 lists the colors of the mononitrides and gives some idea on their color-composition interdependency. These colors can be observed in bulk samples, and also have an important role when thin films<sup>60</sup> are produced for ornamental purposes.

### 6.3 Thermal and Electrical Properties

Interestingly, the transition metal carbides and nitrides do not show the expected decrease in heat conductivities with temperature but instead an increase.<sup>61</sup> Figure 10 illustrates this property for the group 4 nitrides and shows a comparison with group 4 carbides and carbonitrides. The substitution of nitrogen by carbon in group 4 transition metal nitrides significantly reduces the heat conductivities.

The electrical conductivities of transition metal carbides and nitrides are greatly influenced by the nonmetal/metal ratio; as this ratio approaches unity the electrical conductivity reaches a maximum. This is shown for  $\delta$ -TiN<sub>1-x</sub> in Figure 11.<sup>63</sup> A similar behavior can be observed for other carbides and nitrides. The electrical conductivities of these compounds decrease linearly with increasing temperature.<sup>62</sup>

The phenomenon of superconductivity is common for all fcc transition metal nitrides of groups 4 and 5 and is also observed in fcc MoN<sub>1-x</sub> and hexagonal MoN.  $\delta$ -NbN<sub>1-x</sub>

<sup>a</sup>Nitrogen-rich phase boundary depends on nitrogen pressure. <sup>b</sup>Exact composition unknown, probably close to 2:1 (CrN<sub>1-x</sub>, MoN<sub>1-x</sub>) or 1:1 (all others) stoichiometry. <sup>c</sup>X-ray density. <sup>d</sup>Decomposes. <sup>e</sup>Calculated. <sup>f</sup>Not superconducting. <sup>g</sup>Exact composition unknown.

**Figure 10** Heat conductivities of nearly stoichiometric and substoichiometric  $\delta$ -TiN<sub>1-x</sub>,  $\delta$ -ZrN<sub>1-x</sub> and  $\delta$ -HfN<sub>1-x</sub> compared with  $\delta$ -TiN<sub>1-x</sub>,  $\delta$ -ZrC<sub>1-x</sub>,  $\delta$ -HfC<sub>1-x</sub> and  $\delta$ -Ti(C<sub>0.2</sub>N<sub>0.8</sub>) and  $\delta$ -Zr(C<sub>0.2</sub>N<sub>0.8</sub>) as a function of temperature.  $\delta$ -Hf(C<sub>0.2</sub>N<sub>0.8</sub>) coincides closely with the curve for TiN<sup>62</sup>

**Figure 11** Electrical conductivity at room temperature of  $\delta$ -TiN<sub>1-x</sub> as a function of stoichiometry. (Reprinted from Ref. 63. © 1992, with permission from Elsevier)

shows the highest superconducting transition temperature of 17 K, which was the highest known of any material for several decades. It is noteworthy that hexagonal  $\delta$ -MoN also has one of the highest superconducting transition temperatures (15 K) of these materials,<sup>50</sup> and fcc  $\gamma$ -MoN<sub>1.00</sub>, although never prepared with a stoichiometric composition, was predicted theoretically to have a  $T_c$  of up to 30 K. All transition metal nitrides are type II (hard) superconductors. For several fcc nitrides, such as  $\delta$ -TiN<sub>1-x</sub>,  $\delta$ -ZrN<sub>1-x</sub> and  $\delta$ -VN<sub>1-x</sub>,  $T_c$  increases linearly with increasing nitrogen content up to  $[N]/[T] = 1$ ;<sup>64</sup>  $\delta$ -NbN<sub>1-x</sub> shows a much weaker increase. The  $T_c$  data reported for  $\delta$ -HfN<sub>1-x</sub> are contradictory as to whether an increase or a decrease occurs. This is probably due to the fact that  $\delta$ -HfN<sub>1-x</sub> can apparently exist with a hyperstoichiometric composition.  $T_c$  is expected to be reduced significantly by unoccupied metal

sites in the hyperstoichiometric  $\delta$ -VN<sub>1+x</sub>. Figure 12 shows the normalized  $T_c$  of several fcc nitrides (where the highest  $T_c$  of each compound is equal to 1) and Table 1 shows the highest  $T_c$  for each compound for the given composition.

#### 6.4 Thermal Expansion

The thermal expansion of various transition metal nitrides has been measured at both low temperatures<sup>65</sup> (8 K) and high temperatures<sup>66</sup> (up to 1500 K).  $\delta$ -VN<sub>1-x</sub> exhibits a very low or even negative thermal expansion at temperatures below 70 K. The high-temperature thermal expansion data are summarized in Figure 13.<sup>66</sup> Interestingly, considering its low-temperature

**Figure 12** Superconducting transition on temperatures (normalized relative to maximum  $T_c$ ) as a function of stoichiometry for various transition metal nitrides. For  $\delta$ -HfN<sub>1-x</sub>, different functions have been reported (a,b). (Ref. 64. Reproduced by permission of Wiley)

**Figure 13** High-temperature thermal expansion of various transition metal nitrides. (Ref. 54. Reproduced by permission of Materials Information Society/ASM International)

thermal expansion behavior,  $\delta\text{-VN}_{1-x}$  has the highest high-temperature expansion coefficient among these compounds, up to  $11 \cdot 10^{-6}\text{K}^{-1}$  at 1100 K.

### 6.5 Diffusivities

In transition metal nitrides, nitrogen diffusion proceeds via a vacancy mechanism in the nonmetal sublattice. The vacancy concentration is a function of composition within the homogeneity range of the fcc phases and hence the nitrogen diffusivity is most probably composition-dependent as well. However, this has not been generally investigated in transition metal nitrides.<sup>67</sup> In this respect, the Cr–N system has been investigated in detail.<sup>27</sup> Figure 14 shows the concentration-dependent diffusivity in CrN. Generally, diffusivity studies were conducted by investigating nitride layer growth<sup>62</sup> as a function of time, which gives the average nitrogen diffusivity in the various phases. A parabolic relationship,  $d = k \cdot t^{0.5}$ , holds for this layer growth, where  $d$  is the layer thickness,  $k$  is a constant, and  $t$  the diffusion time. The parabolic behavior indicates that the nitride layer growth is indeed diffusion controlled. By use of wedge-type samples, the thickness of diffusion layers is increased if the sample thickness increases. Such a deviation from the parabolic law (if different thicknesses are compared) can be used to establish the nitrogen diffusivities in all the phases at a given temperature.<sup>22,24</sup> An example of such a wedge-type sample is shown in Figure 15 for the Hf–N system.<sup>28</sup>

Nitrogen diffusion in nitrides such as  $\delta\text{-TiN}_{1-x}$ ,<sup>68</sup>  $\delta\text{-ZrN}_{1-x}$  and  $\delta\text{-HfN}_{1-x}$  has an activation energy of 2–3 eV. Although the metal diffusivity in transition metal nitrides has not yet been investigated in detail, the activation energy of that process is probably much higher and can be estimated to be ca. 7–8 eV. Table 2 shows diffusivity data of transition metal nitrides.

The diffusivity versus composition has been investigated for  $\delta\text{-TiN}_{1-x}$ ,  $\delta\text{-HfN}_{1-x}$ ,<sup>28</sup> and  $\delta\text{-NbN}_{1-x}$ .<sup>69</sup> A modified Boltzmann–Matano analysis, carried out on nitrogen diffusion profiles measured by EPMA, yielded a composition-dependent diffusion coefficient for N diffusion expressed as

**Figure 14** Temperature dependence of diffusion coefficients for the Cr–N system obtained from layer growth and concentration profiles,<sup>27</sup> ■/□:  $\delta\text{-CrN}_{1-x}$ , ○/●:  $\beta\text{-Cr}_2\text{N}$ , ▲:  $\alpha\text{-Cr(N)}$

$$D = f v^2 d \exp\left(\frac{-E}{k_B T}\right) \exp(A(c^+ - c)) \text{ cm}^2 \text{ s}^{-1} \quad (5)$$

where  $f = 1/12$ , for fcc compounds,  $v$  is the jump frequency of the N atom,  $d$  is the mean distance between lattice planes,  $E$  is the activation energy,  $k_B$  is the Boltzmann constant,  $A$  is a parameter for the steepness of concentration dependency,  $c$  is the concentration and  $c^+$  is the maximum concentration.

### 6.6 Elastic Properties

Transition metal nitrides exhibit high Young's moduli, appreciably higher than the elastic moduli of the transition

**Figure 15** Wedge-type sample of the Hf–N system with various diffusion layers<sup>28</sup>

metals. As can be seen from Figure 16,<sup>73</sup> the Young's moduli of  $\delta$ -TiN<sub>1-x</sub> and  $\delta$ -ZrN<sub>1-x</sub> increase with increasing nitrogen to metal ratio, whereas for  $\delta$ -HfN<sub>1-x</sub> the modulus remains approximately constant. Several of these data were obtained from thin layers. It is well known that in layers large deviations from bulk properties (lattice parameter, composition) may occur, due probably to the high concentration of defects particularly in PVD layers, while in bulk samples, pores can drastically influence the results.<sup>72</sup>

The elastic properties were critically reviewed by Kral *et al.*<sup>71</sup>

## 6.7 Hardness

Some transition metal nitrides are among the hardest materials known. Figure 17 shows hardness versus composition for  $\delta$ -TiN<sub>1-x</sub> and for the group 5 transition metal nitrides. The hardness decreases with increasing nitrogen content for the group 5 nitrides.<sup>66,70,74</sup> This behavior can probably be explained by electronically induced lattice softening as a result of the generation of antibonding states. It is known from band

**Figure 17** (a) Microhardness of  $\delta$ -TiN. (Reprinted from Ref. 73. © 1992, with permission from Elsevier) and (b) group 5 transition metal nitrides as a function of composition. (Ref. 5. Reproduced by permission of Wiley VCH)

structure calculations that in fcc transition metal compounds with more than eight valence electrons, antibonding states are successively occupied. An increasing valence electron concentration arising from increasing nitrogen content would then lead to a decrease in hardness when the number of valence electrons exceeds eight. Indeed, in  $\delta$ -TiN<sub>1-x</sub> a maximum in microhardness is found at the composition  $\delta$ -TiN<sub>0.67</sub>, corresponding to 7.3 valence electrons. For  $\delta$ -HfN<sub>1-x</sub>, a smooth

increase in microhardness with increasing nitrogen content is observed. This, however, is probably a result of the difference in electronic states owing to 5f electrons.

## 7 USES

Nitrides and carbonitrides in form of powders play some role in hardmetals (cemented carbides). The reader is referred to the article on Carbides of this Encyclopedia (*see Carbides: Transition Metal Solid-state Chemistry*). There, also nitrided hardmetals to form functionally graded hardmetals (FGHM) are discussed.

### 7.1 Wear-resistant and Ornamental Layers

CVD and PVD transition metal nitride layers composed mainly of  $\delta$ -TiN<sub>1-x</sub> and Ti(C,N) are produced in order to increase the service life of hardmetal tools for cutting and milling operations. Nitride-coated tool tips result in a better surface finish of the workpiece owing to both a decrease in diffusion welding between tool tip and workpiece and an increase in thermal oxidation resistance. The layer thickness is generally 1–10  $\mu$ m. Typically, multilayer tools feature layers of TiN, TiC, TiCN, and Al<sub>2</sub>O<sub>3</sub>.<sup>75</sup> Figure 18 shows a multilayer coating including  $\delta$ -TiN<sub>1-x</sub> on a WC-Co hardmetal. Bright golden yellow  $\delta$ -TiN<sub>1-x</sub> is also used for ornamental layers, for example, on watch cases where the combination of color with increased scratch resistance is exploited.

**Figure 18** CVD multilayer coating on WC-Co hardmetal with TiN<sub>1-x</sub> as top and bottom layer

### 7.2 Cemented Carbonitrides

$\delta$ -TiN is used as one of the hard components in sintered hardmetal or cermet compositions containing TiC, Mo<sub>2</sub>C, WC, TaC and other compounds. Such cermets can be produced by liquid phase sintering of blends of TiN and TiC with Mo<sub>2</sub>C and WC and with Ni and/or Co as a binder phase. The modern titanium carbonitride cermets<sup>76</sup> are characterized microstructurally by a structured hard phase featuring a core-rim structure embedded in a tough Co/Ni binder alloy. In steel-cutting applications, such cermets appear to outperform even nitride-coated hardmetal tools.

### 7.3 Diffusion Barriers

Because of their chemical inertness, their high electrical conductivities and the ease with which they can be deposited as layers, transition metal nitrides are excellent candidates for use in multilayer metallizations of integrated circuits.<sup>77,78</sup> In these devices, interdiffusion between the different metals, compound layers or thin metal wires during thermal load with soldering and packaging operations must be avoided, otherwise degradation of the multilayer arrangement will occur. In order to protect these layers against interdiffusion, very thin nitride layers (<100 nm) can be deposited by PVD methods. These layers are stable up to 600 °C (depending on the time and the substrate) and prevent the layers from undergoing structural changes.

## 1 INTRODUCTION

Nitrogen, as an element of the first period, has a tendency to form  $p\pi-p\pi$  double bonds like its neighbors carbon and oxygen. Nitrogen chemistry is therefore different from the chemistry of the heavier homologues (see **Periodic Table: Trends in the Properties of the Elements**). Nitrogen forms element chains (catenation) more easily than its right neighbor oxygen, but less easy than the other neighbors carbon and phosphorus. With the appropriate substituents, nitrogen chains containing up to eight nitrogen atoms are known (see Table 1). Average nitrogen–nitrogen bond distances are 148 pm for single bonds, 120 pm for double bonds, and 110 pm for triple bonds (see **Bond Lengths in Inorganic Solids & Liquids**).

As shown in Scheme 1, nitrogen compounds are known with nitrogen in the oxidation states between  $-3$  and  $+5$ :

In compounds with moderately electropositive bonding partners, nitrogen has the coordination number one ( $N_2$ , HCN), two (angular in  $HN=NH$ , linear in  $Cl-N=O$ ), three (pyramidal in  $NH_3$ ; planar in  $N(SiMe_3)_3$ ),<sup>1</sup> and four (tetrahedral in  $NH_4^+$ ,  $NF_4^+$ ). With more electropositive bonding partners, the higher coordination numbers five (quadratic-pyramidal in  $[Fe_5(CO)_{14}H(\mu_5-N)]$ ), six (octahedral in  $MN$ ,  $M = Sc, Ti, V, Cr, Th, U$ ; trigonal prismatic in  $[Co_6(CO)_{15}(\mu_6-N)]^-$ ) and eight (cubic in  $BeLiN$ ,  $AlLi_3N_2$ ; hexagonal-bipyramidal in  $Li_3N$ ) are known (see **Coordination Numbers & Geometries**). Nitrogen compounds of all nonradioactive elements except

helium, neon, and argon have been isolated, although compounds such as  $XN^+$  with helium, neon, and argon have been detected using mass spectrometry.

Two isotopes of nitrogen are found in nature,  $^{14}N$  (99.634%, magnetic dipole moment  $\mu_N = +0.403761$ , electrical quadrupole moment  $1.60 \times 10^{-30} \text{ m}^{-2}$ ) and  $^{15}N$  (0.366%, magnetic dipole moment  $\mu_N = -0.28319$ , no electrical quadrupole moment).<sup>2</sup> The average mass is 14.00674 atomic mass units. The relation between the isotopes may be different by up to 1.5% for nitrogen from other sources than air, for example, in natural gas or in gas pockets in the Earth's crust.  $^{15}N$  is used for labeling in NMR spectroscopy and mass spectrometry. All other nitrogen isotopes have half-lives that are much too short to be of use in labeling experiments (see Table 2).

Fractional distillation of  $^{15}NO$  is an effective method for concentrating  $^{15}N$ . Chemical exchange processes for nitrogen isotope separation include the following:

The  $NO-NO_2$  equilibrium can be used in thermal diffusion separation.

## 2 DINITROGEN

In 1772, the German Carl Scheele, the Englishman Henry Cavendish, the Scotsman Daniel Rutherford, and Joseph Priestley, who was also English, all independently discovered dinitrogen or studied its equivalent, 'burnt' air or air where the oxygen was removed. A. L. Lavoisier named it azôte (from the Greek word meaning 'lifeless'). After niter (potassium nitrate) and nitric acid were recognized as compounds of the element, the name nitrogenium (Latin, 'niter former') was introduced by the French J. A. C. Chaptal.<sup>3,4</sup>

Nitrogen occurs almost exclusively in nature as dinitrogen  $N_2$ . It is the main part of dry air (78.09% by volume, 75.52% by weight), which accounts for more than 99% of the approximately  $10^{15}$  tons of nitrogen on earth. At higher altitudes, dinitrogen is partly dissociated to nitrogen by ultraviolet radiation. Other nitrogen species with very short lifetimes are also formed under stratospheric conditions. The high solubility of nitrogen salts makes minerals containing nitrogen, mainly nitrates, rare. The major minerals are saltpeter  $KNO_3$ , occurring in large deposits in India and Chile saltpeter  $NaNO_3$ , which can be found in the desert sections of northern Chile. Calcium nitrate, ammonium chloride, and several other compounds can occasionally be found in small amounts. Another  $10^{13}$  tons of dinitrogen are

**Scheme 1** Examples of nitrogen compounds in various oxidation states**Table 1** Examples of nitrogen chains

| 8    | N=N-N-N=N-N-N-N | PhN=N-N(Ph)-N=N-N(Ph)-<br>N=NPh                                                                                |

dissolved in the oceans. Like many other gaseous compounds, dinitrogen is also included in water clathrate complexes, for example (H<sub>2</sub>O)<sub>136</sub>(N<sub>2</sub>)<sub>9.4</sub>, which was found in Greenland. Extraterrestrially, nitrogen has been detected in the atmosphere of Mars (2.7 vol%), Venus (3.5 vol%), Pluto, and possibly in traces on Mercury. Nitrogen also occurs in proteins and other organic compounds in the biosphere (10<sup>10</sup> t). It is an essential element for humans; the human body contains about 3% nitrogen, which is found in proteins, DNA, and many coenzymes. There are several processes, referred to as nitrogen fixation, making dinitrogen available to biological species. In

lightning, enough energy is set free to activate dinitrogen molecules for the reaction with dioxygen, forming nitrogen oxides. Industrial nitrification is discussed in Section 5.1.1. Some bacteria can form ammonia from dinitrogen (*see Nitrogenase: Metal Cluster Models and Nitrogenase Catalysis & Assembly*). In the nitrification process, ammonia is converted to nitrate via nitrite by bacteria under aerobic conditions. In anaerobic conditions, bacteria convert nitrate via nitrite to the gaseous compounds NO, N<sub>2</sub>O, and N<sub>2</sub>.

## 2.1 Production of Dinitrogen

The technical production of dinitrogen and other nitrogen compounds is discussed in great detail in the literature.<sup>5</sup> A compilation of physical data for many compounds is published.<sup>6</sup> For all technical processes, dinitrogen is obtained from air, where cryogenic (low temperature), adsorption, and membrane separation processes are used. The chemical removal of dioxygen from air is an older method that is of secondary importance. The cryogenic production is based on the fractionized distillation of liquid air. Nitrogen production by pressure-swing adsorption (PSA) employs carbon or zeolitic molecular sieves. Separation of air components with zeolites is based on differences in adsorption capacity; carbon molecular sieves employ differences in diffusion rates. In

carbon molecular sieves, the unadsorbed  $N_2$ -rich gas product is withdrawn at the discharge end of the adsorber during the adsorption phase. In the zeolite process, previously adsorbed nitrogen is recovered by lowering the pressure during the regeneration phase. The membrane separation process uses membranes that have different permeabilities for different gases. The total nitrogen production in Europe, the United States, and Japan amounted to  $59.6 \times 10^9 \text{ m}^3$  in 1996. The production of gaseous nitrogen is growing more rapidly than that of liquid nitrogen. The largest applications need dinitrogen gas and have, therefore, always been most economically served by gas. Today, noncryogenic production technologies such as membranes and PSA are making gas production economical at customer sites.

Nitrogen from the cryogenic distillation of air has an inherent high purity since virtually all bulk gases with higher boiling points (methane, water, carbon dioxide) are removed to less than ppb levels by volume. The very low boiling gases helium, hydrogen, and neon are not removed by standard single-column cryogenic processes, nor is carbon monoxide, which is difficult to separate by cryogenic fractionation because of its boiling point of 81.6 K. CO and  $H_2$  can be removed from the compressed air before distillation by oxidation in an upstream catalytic reactor with a noble metal catalyst. The oxidation products are water and carbon dioxide, which can be removed by the conventional air-purification system. Downstream purifier systems operate by oxidation over metal oxides and chemisorption by transition metals. Thus, nickel at ambient temperature eliminates oxygen as the oxide and hydrogen as the hydride.

In a chemical process, oxygen can be removed from air ( $4N_2 + O_2$ ) by oxidation with carbon, propane gas, or ammonia and successive removal of carbon dioxide and water. Because air also contains noble gases, chemical processes do not yield pure dinitrogen but a mixture of dinitrogen and noble gases.

Partial burning of carbon produces carbon monoxide (see Section 5.1.1):

In the laboratory, copper can be used to bind oxygen at red heat:

Pure dinitrogen can be obtained from nitrogen compounds, for example, the oxidation of ammonia with  $CaCl(OCl)$  or bromine. More often, nitrous acid is used to include the nitrogen of the acid:

The thermal decomposition of azides, especially of sodium azide, is used to produce spectroscopically pure dinitrogen:

The largest-volume of dinitrogen is used for the synthesis of ammonia. As an alloying element in steel, nitrogen serves to improve hardness and corrosion resistance. The inert dinitrogen is used as a blanketing gas to prevent oxidation or fire. It is also used for the processing, cooling, storage, and transportation of food. Liquid nitrogen provides the cryogenic temperature necessary for freezing, and nitrogen vapor as an inert medium inhibits oxygen-dependent ripening and decay processes. Embrittlement of grinding feed, shrink fitting of metal parts, cryosurgery, or the conservation of biological samples are only a few examples of the many uses of liquid nitrogen.

## 2.2 Physical Properties of Dinitrogen

Dinitrogen is a colorless, odorless, noncombustible gas with a density of  $1.2505 \text{ g dm}^{-3}$  at standard conditions ( $C_p = 29.12 \text{ J mol}^{-1} \text{ K}^{-1}$ ). The boiling point is 77.36 K (enthalpy of vaporization:  $5.577 \text{ kJ mol}^{-1}$ ) and the melting point is 63.15 K (enthalpy of fusion:  $0.7196 \text{ kJ mol}^{-1}$ ) (see Table 3). Two solid phases of dinitrogen exist (see Table 4), the standard  $\beta$ -phase (hexagonal close-packed  $N_2$  molecules) and the  $\alpha$ -phase (cubic close-packed  $N_2$  molecules). The standard enthalpy of transition is  $228.9 \text{ kJ mol}^{-1}$ . At pressures above 350 Mpa, tetragonal  $\gamma$ - $N_2$  is formed. Gaseous dinitrogen has a specific heat capacity of  $1.040 \text{ J g}^{-1} \text{ K}^{-1}$ , a dynamic viscosity of  $15.9 \times 10^{-6} \text{ Pa}$  and a thermal conductivity of  $25.9 \text{ mW m}^{-1} \text{ K}^{-1}$  (298).

The bond distance in  $N_2$  is 109.75 pm and the bond dissociation energy of the N–N triple bond is  $945.33 \text{ kJ mol}^{-1}$ .

$N_2$  is soluble in metal melts, for example, 4% dinitrogen can be solved in iron melts. Dinitrogen is only half as soluble as dioxygen in water (see Table 5). This is important for

**Table 3** Properties of  $N_2$ <sup>7</sup>

the breathing of marine life. Dinitrogen has no apparent effect on plants, animals, or humans. Suffocation in dinitrogen atmosphere is due to the lack of dioxygen. The higher solubility of dinitrogen in blood at high pressures is responsible for decompression sickness and nitrogen narcosis, known as the ‘bends’, in divers.

### 2.3 Chemical Properties of Dinitrogen

Dinitrogen is relatively inert under standard conditions due to the high stability of the nitrogen–nitrogen triple bond. This makes most reactions of dinitrogen endothermic. Exothermic reactions of dinitrogen have high activation barriers. Unlike dioxygen (IE 13.618 eV), dinitrogen cannot be oxidized chemically to the cation  $\text{N}_2^+$  because of the high ionization energy of dinitrogen (15.576 eV).<sup>4</sup>

The reactivity of the  $\text{N}_2$  molecule increases rapidly as the temperature is increased. At higher temperatures, compounds with many metals and nonmetals are formed. Binary nitrogen compounds, which sometimes cannot be obtained by the direct reaction, have been found for most elements. Binary noble-gas nitrogen compounds have been detected mass spectrometrically (e.g.  $\text{XN}^+$ ,  $\text{XN}_2^+$ ). Among the prominent reactions of dinitrogen are the reaction of dinitrogen with hydrogen to form ammonia (in detail see Section 5.1.1), the reaction of dinitrogen with dioxygen at elevated temperatures to form NO (in details see Section 7.8.1), and the reaction of dinitrogen with calcium carbide at 1300 K ( $\Delta H = -296 \text{ kJ mol}^{-1}$ ) to form calcium cyanamide, which is used for nitrogen fixation.

While the latter reactions are no longer used for nitrogen fixation, the reaction of dinitrogen with dihydrogen to form ammonia is among the most important industrial processes. The alkaline-earth metals react readily with dinitrogen at elevated temperatures to form nitrides; lithium reacts even at room temperature with dinitrogen.

The nitrides (see *Nitrides: Transition Metal Solid-state Chemistry*) can be divided roughly into ionic nitrides (e.g. alkali and alkaline-earth nitrides), covalent nitrides (e.g.

BN (see *Boron: Inorganic Chemistry*),  $\text{S}_4\text{N}_4$  (see *Sulfur–Nitrogen Compounds*),  $\text{CN}_2$  (see *Carbon: Inorganic Chemistry*),  $\text{S}_2\text{N}_2$  (see *Sulfur–Nitrogen Compounds*),  $\text{As}_4\text{N}_4$ ,  $\text{P}_3\text{N}_5$ ,  $\text{Ge}_3\text{N}_4$ ,  $\text{Se}_4\text{N}_4$  (see *Selenium: Inorganic Chemistry*),  $\text{Te}_4\text{N}_4$  (see *Tellurium: Inorganic Chemistry*), and semimetallic phases (VN, CrN,  $\text{W}_2\text{N}$ ). In semimetallic phases, the nitrogen atoms are interstitial or included in more complex structures. The nitride ion,  $\text{N}^{3-}$ , is only stable with very Lewis basic cations. Even in the alkaline-earth metal nitrides  $\text{M}_2\text{N}_3$  ( $\text{M} = \text{Be–Ba}$ ), the metal–nitrogen bond has a covalent contribution.

Nitrogen can form complexes with compounds of most transition metals. These play an important role in the biological nitrogen fixation process (see *Nitrogenase: Metal Cluster Models* and *Nitrogenase Catalysis & Assembly*), where bacteria use dinitrogen complexes to form other nitrogen compounds. Metal complexes of dinitrogen can be synthesized directly from the reaction of dinitrogen with metal salts in a reducing environment (10) or by the oxidation of metal coordinated ammonia (11) or hydrazine (12).

The dinitrogen ligand is often easily displaced by other ligands. Some dinitrogen complexes can be reduced to ammonia or hydrazine complexes and are model compounds for the biological nitrogen fixation process. Homoleptic metal dinitrogen complexes  $\text{M}(\text{N}_2)_x$  are not stable at standard conditions but can be obtained by the rapid chilling of metal/dinitrogen gas mixtures below 10 K (e.g.  $\text{Ti}(\text{N}_2)_6$ ,  $\text{V}(\text{N}_2)_6$ ,  $\text{Cr}(\text{N}_2)_6$ ,  $\text{Rh}(\text{N}_2)_4$ ,  $\text{Ni}(\text{N}_2)_4$ ,  $\text{Pd}(\text{N}_2)_3$ ,  $\text{Pt}(\text{N}_2)_3$ ). These compounds are metastable at low temperatures and loose dinitrogen upon warming.  $\text{Ti}(\text{N}_2)_6$  decomposes at 40 K.

As shown in Scheme 2, most dinitrogen complexes show a  $\sigma$  end-on coordination of the dinitrogen molecule (**1**) (e.g. octahedral  $[\text{Os}(\text{NH}_3)_4(\text{N}_2)_2]^{2+}$ ). The end-on coordination (**2**) is also found for bridging dinitrogen ligands (e.g.  $[\{\text{Ru}(\text{NH}_3)_5\}_2\text{N}_2]^{2+}$ ). Side-on coordination via the  $\text{N}_2\pi$ -orbitals has been found in very few complexes. Planar side-on coordinated dinitrogen (**3**) is found in  $\{(\text{C}_5\text{Me}_5)_2\text{Sm}\}_2(\text{N}_2)$ . In some zirconium complexes, for example,  $[(i\text{Pr}_2\text{PCH}_2\text{SiMe}_2)_2\text{N}]\text{ZrCl}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-N}_2)$ , a bent coordination (**4**) is found. (see *Nitrogenase: Metal Cluster Models* and *Nitrogenase Catalysis & Assembly*).

**Scheme 2** Coordination of dinitrogen in transition metal complexes

### 3 ATOMIC NITROGEN

An electric discharge in a  $N_2$  atmosphere in the pressure range 1.0–0.1 hPa splits dinitrogen molecules to atomic nitrogen. This is accompanied by a peach–yellow glow that persists for up to 6 h after stopping the discharge.<sup>8</sup>

Atomic nitrogen ( $\Delta H_f = 472.7 \text{ kJ mol}^{-1}$ ) is very reactive. It reacts with many metals to form nitrides at room temperature.

Atomic nitrogen also reacts with nonmetals like phosphorus and sulfur (see **Phosphorus–Nitrogen Compounds** and **Sulfur–Nitrogen Compounds**).

Recombination of the nitrogen atoms to  $N_2$  is a slow process since it requires a three-body collision of the nitrogen atoms with the walls of the container or a termolecular, homogeneous second-order association of the nitrogen atoms. This can result in excited dinitrogen molecules that are responsible for the yellow glow.

The excited dinitrogen molecules  $N_2^*$  can break bonds in other molecules:

Nitric oxide NO molecules can be used to determine the concentration of the nitrogen atoms.

This rapid reaction stops the yellow glow. If excess NO is present, the oxygen atoms react with NO to form  $\text{NO}_2$  under emission of a green–yellow light:

whereas a blue light is emitted if not enough nitrogen oxide is present:

### 4 POLYNITROGEN

In contrast to the other elements, the homonuclear single-bond energies of nitrogen ( $159 \text{ kJ mol}^{-1}$ ) (and oxygen) are significantly less than one-third of their triple ( $945.33 \text{ kJ mol}^{-1}$ ) or one-half of their double-bond ( $466 \text{ kJ mol}^{-1}$ ) energies (see **Main Group: Multiple Bonding**). Compounds with high nitrogen content are synthesized for use as high-energy materials.<sup>9</sup> The nitrogen–nitrogen double bond energy is also less than two-thirds of the triple bond energy. As a consequence, ordinary nitrogen consists of diatomic molecules, which are very stable and remarkably unreactive and reluctant, in particular, to bind to other N atoms to give  $N_n$  species with  $n > 2$ . Homonuclear polynitrogen species are thermodynamically highly unstable, since invariably their dissociation into  $N_2$  is highly exothermic, and there are only very few compounds known.<sup>10</sup> Owing to the highly endothermic heats of formation, their syntheses and handling present great challenges. No nitrogen compounds are known that can be isolated in bulk, while most other elements can exist in the form of many stable allotropes. Owing to the great experimental difficulties, most polynitrogen species have only been studied theoretically. Molecular nitrogen forms a non-molecular superconductor that exists at equilibrium over a very large range of pressures, from below 100 GPa to at least 240 GPa.

#### 4.1 Trinitrogen

The azide radical  $N_3\cdot$  (linear, ground state  $^2\Pi_g$ ,  $d(\text{N–N})$  118.1 pm) is produced in the reaction of  $\text{HN}_3$  with fluorine atoms ( $\Delta H_r = -180 \text{ kJ mol}^{-1}$ ):

The enthalpy of formation of the azide radical is  $467 \pm 8 \text{ kJ mol}^{-1}$ . The spin-allowed dissociation to  $\text{N}(^2\text{D})$  and  $\text{N}_2(\text{X } ^1\Sigma_g^+)$  is endoergic by  $225 \text{ kJ mol}^{-1}$ , the dissociation enthalpy to  $\text{N}(^4\text{S}) + \text{N}_2(\text{X } ^1\Sigma_g^+)$  is  $-0.5 \pm 1 \text{ kJ mol}^{-1}$ .<sup>11</sup> The azide radical is only stable because this spin-forbidden decomposition pathway has an appreciable energy barrier. In aqueous solution, it primarily exists as a monomer, in contrast to other halide or pseudohalide radicals that exist as the less reactive dimers (e. g.  $\text{Br}_2^{\cdot-}$ ,  $(\text{SCN})_2^{\cdot-}$ ). Reaction of the azide radical with halogen atoms or other small molecules like  $\text{O}_2$ , NO, CO, and  $\text{CO}_2$  produces molecules in electronically excited states because of propensity rules, which can be used for chemically pumped lasers.<sup>12</sup> The azide ion is also formed during high-pressure photolysis of sodium azide.

##### 4.1.1 $N_3^+$

The trinitrogen cation is produced in nitrogen plasmas through the reaction of energized  $\text{N}_2^+$  ions with  $\text{N}_2$  molecules. Formation in the atmosphere probably involves ternary

reactions of  $\text{N}^+$  and  $\text{N}_2$ .<sup>13</sup> In the atmosphere, it reacts with  $\text{H}_2\text{O}$  to form  $\text{H}_2\text{NO}^+$  and with  $\text{O}_2$  to form  $\text{NO}^+$ .  $\text{N}_3^+$  ( $X^1\Sigma_g^+$ ) has a linear, centrosymmetric structure like the azide radical and the azide anion ( $D_{\infty h}$ ,  $d(\text{N}-\text{N}) = 119.3 \text{ \AA}$ ). It is quite strongly bound with a dissociation energy of about 3.5 eV:

Attempts to remove the fluorine atom of  $\text{N}_3\text{F}$  with the strong fluorine acceptors  $\text{AsF}_5$ ,  $\text{SbF}_5$ , or  $\text{BF}_3$  only yielded the adducts  $\text{N}_3\text{F}\cdot\text{AsF}_5$  and  $\text{FN}_3\cdot\text{BF}_3$  and explosions in the case of  $\text{SbF}_5$ . The  $\text{N}_3^+$  cation was not observed in this reaction.<sup>14</sup> Electrostatically bound  $(\text{N}_3)^+-(\text{N}_2)_n$  clusters have been observed mass spectrometrically.<sup>15</sup>

The azide ion is discussed in Section 5.8.

## 4.2 Tetranitrogen

The metastable singlet  $T_4$  species tetraazatetrahedrane (**5**) shown in Scheme 3 is the best theoretically investigated  $\text{N}_4$  species. The dissociation to  $\text{N}_2$  has an activation energy of  $54 \text{ kJ mol}^{-1}$  to release as much as  $800 \text{ kJ mol}^{-1}$  of energy. Density functional calculations show the open-chain  $C_{2h}$  triplet (**6**), which releases  $505 \text{ kJ mol}^{-1}$  upon decomposition, to be the global minimum structure whereas a MP4 study shows it to be a transition state and identifies the  $C_s$  triplet (**7**) as the global minimum. The metastable  $D_{2h}$  singlet (**8**), which releases  $766 \text{ kJ mol}^{-1}$  upon decomposition, was also found at the B3LYP level.

A van-der-Waals dimer  $(\text{N}_2)_2$  with a dissociation energy of only about  $1 \text{ kJ mol}^{-1}$  has been detected experimentally. Another  $\text{N}_4$  species, which was prepared by neutralizing  $\text{N}_4^+$ , was detected mass spectrometrically,<sup>16</sup> and is believed to be the  $C_s$  triplet because of its fragmentation pattern. The geometry of the starting material  $\text{N}_4^+$  also points to a linear structure.

### 4.2.1 $\text{N}_4^+$

The  $\text{N}_4^+$  cation is formed in electric discharges through nitrogen.<sup>17</sup>  $\text{N}_2^+$  is formed by interaction of cosmic rays with  $\text{N}_2$  in the stratosphere and can, in denser regions of the ionosphere, form  $\text{N}_4^+$ , which might play a role as an intermediate that reacts very rapidly with other species in the atmosphere.  $\text{N}_4^+$  ( $X^2\Sigma_u^+$ ) has a linear, centrosymmetric structure. The dissociation energy to  $\text{N}_2$  ( $X^1\Sigma_g^+$ ) and  $\text{N}_2^+$  ( $X$

**Scheme 3** Connectivity of theoretically predicted  $\text{N}_4$  isomers

$^2\Sigma_u^+$ ) is only slightly higher than  $96 \text{ kJ mol}^{-1}$ . The terminal N–N bond is with  $110.9 \text{ pm}$  slightly longer than in  $\text{N}_2$  and slightly shorter than in  $\text{N}_2^+$  ( $111.6 \text{ pm}$ ). The inner N–N bond is with  $200.4 \text{ pm}$  rather long. Mass spectrometrically observed  $(\text{N}_2)_n^+$  clusters contain a  $\text{N}_4^+$  core.

## 4.3 Pentanitrogen

While the symmetric, weak complex between a  $\text{N}_3\cdot$  radical and  $\text{N}_2$  (**9**) in Figure 1 was shown to be minimum on the potential surface, higher-level computations indicate that this complex is not stable.<sup>18</sup>

### 4.3.1 $\text{N}_5^+$

The pentanitrogen cation has an essentially planar V-shape structure ( $C_{2v}$ ). The exceptional stability of  $\text{N}_5^+$  is largely due to resonance stabilization shown in Scheme 4, resulting in relatively high bond orders for all the bonds.<sup>19</sup> The additional, higher charged Lewis structures in the second row have to be included to account for the charge distribution of  $\text{N}_5^+$ .<sup>20</sup> The geometrical parameters of the pentanitrogen cation in  $\text{N}_5^+\text{Sb}_2\text{F}_{11}^-$  are shown in Table 6.

**Figure 1** Connectivity of  $\text{N}_5$  minimum structure

**Scheme 4** Mesomeric structures of  $\text{N}_5^+$

**Table 6** Geometrical parameters of the pentanitrogen cation in  $\text{N}_5^+\text{Sb}_2\text{F}_{11}^-$

|                               |        |                                             |        |
|-------------------------------|--------|---------------------------------------------|--------|
| $d(\text{N1}-\text{N2})$ [pm] | 110(2) | $d(\text{N4}-\text{N5})$ [pm]               | 111(2) |
| $d(\text{N2}-\text{N3})$ [pm] | 130(2) | $\angle(\text{N1}-\text{N2}-\text{N3})$ [°] | 168(2) |
| $d(\text{N3}-\text{N4})$ [pm] | 130(2) | $\angle(\text{N2}-\text{N3}-\text{N4})$ [°] | 111(1) |

The reaction of  $\text{N}_2\text{F}^+\text{MF}_6^-$  salts ( $\text{M} = \text{As}, \text{Sb}$ ) with  $\text{HN}_3$  yields the  $\text{N}_5^+$  cation ( $\text{C}_{2v}$ ).<sup>21</sup>

Using the insolubility of  $\text{KSbF}_6$  in  $\text{SO}_2$  and of  $\text{CsSbF}_6$  in  $\text{HF}$ , salts of  $\text{N}_5^+$  have been prepared in metathetical reactions:

$(\text{N}_5^+)_2\text{SnF}_6^{2-}$  is only marginally stable at room temperature and decomposes at slightly higher temperatures yielding  $\text{N}_5^+\text{SnF}_5^-$  and  $\text{FN}_5$ , which has a lifetime of nanoseconds and decomposes instantly to dinitrogen and fluorine azide, whose further decomposition yields several  $\text{NF}$  compounds (see Section 8.6).

While  $\text{N}_5^+\text{AsF}_6^-$  and  $(\text{N}_5^+)_2\text{SnF}_6^{2-}$  are only marginally stable at room temperature and decompose at slightly elevated temperatures, the decomposition of  $\text{N}_5^+[\text{B}(\text{CF}_3)_4]^-$  starts at 323 K and the decomposition of  $\text{N}_5^+\text{SbF}_6^-$  and  $\text{N}_5^+\text{Sb}_2\text{F}_{11}^-$  at 343 K, thus indicating the limits of the thermal stability of the  $\text{N}_5^+$  ion.

$\text{N}_5^+\text{SbF}_6^-$  oxidizes  $\text{NO}$ ,  $\text{NO}_2$ , and  $\text{Br}_2$ , but does not oxidize  $\text{Cl}_2$ ,  $\text{O}_2$ , or  $\text{Xe}$ , indicating an ionization potential between 10.52 and 11.48 eV.

So far,  $\text{N}_5^+$  has not been combined with a polynitrogen anion to form a new modification of nitrogen. Theoretical consideration and experimental investigations agree that  $\text{N}_5^+\text{N}_3^-$  is not stable. However, calculations indicate that the salt  $\text{N}_5^+\text{N}_5^-$  may be stable.<sup>22</sup>

#### 4.3.2 $\text{N}_5^-$

Both pentazole  $\text{N}_5\text{H}$  and the pentazole anion  $\text{N}_5^-$  consist of a five-membered ring of nitrogen atoms. Huisgen and Ugi synthesized the first pentazole derivatives  $\text{RN}_5$  with substituted phenyl rings.<sup>23</sup> Tetrazolylpentazole and imidazolylpentazole, the pentazole derivatives of five-membered aromatic rings, are also known.<sup>24</sup> The geometry of the pentazole ring system was determined from the crystal structures of *p*-dimethylaminophenylpentazole, which decomposes at 340 K, and phenylpentazole (see Table 7). The pentazole ring system is planar with almost equal N–N distances.

Kinetic studies on *p*-substituted phenylpentazoles have demonstrated that electron-donating substituents on the phenyl ring such as  $\text{NMe}_2$  and electron-withdrawing substituents such

**Table 7** Geometrical parameters of the pentazole ring system in phenylpentazole

|               |          |              |          |
|---------------|----------|--------------|----------|
| d(N1-N2) [pm] | 132(1)   | N1-N2-N3 [°] | 105.3(1) |
| d(N2-N3) [pm] | 130.8(2) | N2-N3-N4 [°] | 108.9(1) |
| d(N3-N4) [pm] | 133.7(6) | N3-N4-N5 [°] | 109.0(1) |
| d(N4-N5) [pm] | 130.7(8) | N4-N5-N1 [°] | 105.3(1) |
| d(N1-N5) [pm] | 132.2(2) | N2-N1-N5 [°] | 111.5(1) |

as  $\text{NO}_2$ , respectively increase and decrease the stability of pentazole with respect to decomposition. Thus, maximum negative charge in the pentazole ring leads to the most stable compounds. Therefore, the pentazole anion  $\text{N}_5^-$  is the most stable pentazole species with an estimated activation energy of decomposition of  $116\text{ kJ mol}^{-1}$ , and a reaction enthalpy of  $60\text{ kJ mol}^{-1}$  for the decomposition forming the azide ion and  $\text{N}_2$ .<sup>25</sup> Pentazole  $\text{N}_5\text{H}$  has an estimated activation energy of  $68\text{ kJ mol}^{-1}$  for the decomposition to dinitrogen and hydrazoic acid. NMR spectroscopic studies yielded accurate kinetic data for the decomposition of arylpentazoles (see Scheme 5), and proved that the pentazole ring is relatively stable in solution. On reaction of an azide ion with an aryl diazonium compound, three open-chain  $\text{ArN}_5$  compounds are formed.<sup>26</sup> One isomer (*Z*, *E*) decomposes instantly to phenylazide and dinitrogen, another (*E*, *E*) can rearrange to a third isomer (*E*, *Z*), which can also be formed directly and undergoes cyclization to form a pentazole. Decomposition follows a different mechanism: phenylpentazole is involved in a 1,3-dipolar cycloreversion with elimination of dinitrogen to form phenylazide.

With negative ion electrospray ionization of *p*-hydroxyphenylpentazole and laser desorption ionization of *p*-dimethylaminophenylpentazole, it was possible to cleave the C–N bond between the aromatic substituent and the pentazole in  $\text{R–N}_5$  and to observe the pentazole anion mass spectrometrically.<sup>27</sup>

#### 4.4 Hexanitrogen

Quantum chemical calculations of the  $\text{N}_6$  potential-energy hypersurface have shown that the qualitative shape strongly depends on the choice of the theoretical method and basis set. All the geometries represented in Scheme 6 have been shown to be minima on the potential surface, but most of them do not possess minima at all the levels of theories applied. Hexaazabenzene (**13**), for example, has a minimum for a  $D_{6h}$  structure at the HF level of theory. However, this geometry is a second-order saddle point with the density functional theory (DFT) and also at the MP2 level of theory.  $D_2$  hexaazabenzene has a minimum structure at DFT, but at the CCSD(T)/aug-cc-pVDZ level, the  $D_2$  geometry resembles a van der Waals complex of two  $\text{N}_3$  units, whereas it is a minimum structure at the CCSD(T)/cc-pVTZ level of theory. Similar behavior has been observed for most of the other isomers.

Only the first two compounds, an open-chain diazide (**10**)<sup>28</sup> and hexaazadewarbenzene (**11**) have minima at all levels of

**Scheme 5** Formation and decomposition of the pentazole ring system

**Scheme 6** Connectivity for calculated geometries of  $\text{N}_6$

theory applied. The diazide (10) has a planar *trans*-  $\text{C}_{2h}$  structure and is the global minimum structure for  $\text{N}_6$ , the  $\text{C}_{2v}$  hexaazadewarbenzene (11) is  $230 \text{ kJ mol}^{-1}$  higher in energy. The diazide (10) decomposes with a concerted elimination of two  $\text{N}_2$  molecules. The decomposition barrier is estimated to be about  $70\text{--}80 \text{ kJ mol}^{-1}$ .<sup>18</sup>

**Scheme 7** Connectivity of calculated  $\text{N}_6^-$  isomers

#### 4.4.1 $\text{N}_6^-$

The reaction of the azide radical  $\text{N}_3^\bullet$  with excess azide ions in solution forms the hexanitrogen radical anion ( $\Delta H = 18 \text{ kJ mol}^{-1}$ ).<sup>29</sup>

The hexanitrogen radical anion is more stable in acetonitrile solution compared to water. In the absence of added quenchers,

it decays with approximately second-order kinetics with a half-life of  $10 \mu\text{s}$ . During the high-pressure photolysis (1.1 GPa) of sodium azide,  $\text{N}_6^-$  ions have also been detected.

Using quantum chemical calculations, the two minima in Scheme 7 have been found for  $\text{N}_6^-$ . Both are formal dimers of  $\text{N}_3$  with large distances between the azide units.

At the highest level of theory applied, the *trans* form (19) was calculated to be more stable than the rectangular form (20) by about  $2 \text{ kJ mol}^{-1}$ .<sup>18</sup>

Figure 2 Connectivity of  $N_7$  minimum structure

#### 4.5 Heptanitrogen

A  $C_{2v}$  open-chain structure (21) in Figure 2 was found to be the global minimum structure for  $N_7$ , but complications of the calculations suggest that neutral  $N_7$  does not have a significant dissociation barrier similar to  $N_5$ .<sup>30</sup>

For  $N_7^+$ , an open-chain structure (22) shown in Figure 3 and similar to (21), which was found for  $N_7$ , was calculated. The decomposition of the open-chain  $N_7^+$  to the  $N_5^+$  cation and dinitrogen has a calculated activation barrier of 13  $\text{kJ mol}^{-1}$ .<sup>31</sup>

For  $N_7^-$ , the open-chain  $C_2$  structure (23) in Scheme 8 is the global minimum. It is favored by 36  $\text{kJ mol}^{-1}$  over the complex  $C_s$  structure (25) and 45  $\text{kJ mol}^{-1}$  over the  $C_s$  ring structure (24). The activation energy for the decomposition was calculated to be 5  $\text{kJ mol}^{-1}$  for the open-chain structure (23), which decomposes to the azide anion and two molecules of dinitrogen and to 18  $\text{kJ mol}^{-1}$  for the ring structure (24).<sup>31</sup>

Figure 3 Connectivity of  $N_7^+$  minimum structure

Scheme 8 Connectivity of calculated  $N_7^-$  isomers

Scheme 9 Connectivity of calculated  $N_8$  isomers

#### 4.6 Octanitrogen

Several isomers of  $N_8$  have been studied theoretically (see Scheme 9).<sup>32</sup> Azidopentazole (26) is the global minimum structure (964  $\text{kJ mol}^{-1}$  above 4  $N_2$ ). Octaazapentalene (27) is 72  $\text{kJ mol}^{-1}$  higher in energy, *cis*-(29) and *trans*-(28) diazodiiimide ( $N_3-N=N-N_3$ ) are 58  $\text{kJ mol}^{-1}$  and 63  $\text{kJ mol}^{-1}$  higher in energy and octaazacubane (30) is 939  $\text{kJ mol}^{-1}$  higher in energy.

Azidopentazole (26) is believed to decompose forming four dinitrogen molecules (activation energy 59  $\text{kJ mol}^{-1}$ ). The violently explosive tetrazolylazide, which is derived from azolypentazole by the exchange of one nitrogen with a carbon atom and the addition of a hydrogen atom, shows the high-energy content of these systems.<sup>33</sup> Octaazapentalene (27) decomposes by rearrangement to azidopentazole (26) (activation energy 37  $\text{kJ mol}^{-1}$ ) and the diazodiiimides (28) and (29) decompose via elimination of a dinitrogen molecule (activation energies: *cis* 80  $\text{kJ mol}^{-1}$ , *trans* 91  $\text{kJ mol}^{-1}$ ). The least motion unimolecular decomposition of octaazacubane (30) to four dinitrogen molecules is spin forbidden, as is the case also for its hydrocarbon analogue cubane  $C_8H_8$ . However, a non-least-motion pathway was found that reduces the activation barrier to less than 80  $\text{kJ mol}^{-1}$ .

#### 4.7 Nonanitrogen

For the decomposition of the  $C_{2v}$  open-chain nonanitrogen  $N_9$  (31), in Figure 4 to open-chain  $N_7$  (28) and  $N_2$ , a dissociation barrier of 69  $\text{kJ mol}^{-1}$  was calculated.<sup>34</sup> Bearing in mind that no true minimum structures for  $N_5$  and  $N_7$  have been found, the calculated dissociation barrier for  $N_9$  seems to be too high.

#### 4.8 Decanitrogen

The  $C_{3v}$  triazidoamine (33) in Scheme 10 represents a minimum structure at lower levels of theory; at the MP2 level, however, it does not represent a minimum. Dipentazole ( $D_{2d}$ ) (32) decomposes to azidopentazole (26) and dinitrogen

Figure 4 Connectivity of  $N_9$  minimum structure

**Scheme 10** Connectivity of calculated  $N_{10}$  isomers

with an activation barrier of  $21.2 \text{ kJ mol}^{-1}$ .<sup>25</sup> It is very improbable that dipentazole (32) can be isolated, because the activation energy for the decomposition of the experimentally known tetrazolypentazole, where one nitrogen atom is exchanged by carbon, was calculated by the same method to be  $48 \text{ kJ mol}^{-1}$ , and tetrazolypentazole decomposes at temperatures above 220 K.<sup>24</sup> Calculations have shown that the activation energy for the decomposition of azolypentazoles decreases with an increasing number of nitrogen atoms in the five-membered ring. Imidazolypentazole, which has two nitrogen atoms, decomposes above 248 K. Therefore, dipentazole could only be observed at temperatures that are below 200 K, maybe much below 200 K. The activation energy for the decomposition of open-chain  $C_{2h}$   $N_{10}$  (34) to open-chain  $N_8$  (28) and dinitrogen was calculated to be  $64 \text{ kJ mol}^{-1}$ . The  $C_s$  pentazole isomer (35) has an activation energy of  $49 \text{ kJ mol}^{-1}$  for the decomposition to open-chain  $N_8$  (28) and dinitrogen. Calculations also indicate that salts of the type  $N_5^+N_5^-$  with the experimentally known  $N_5^+$  and  $N_5^-$  ions are stable against charge transfer reactions between the ions. A  $N_5^+N_5^-$  salt is the most likely candidate for the synthesis of solid nitrogen.<sup>22</sup>

#### 4.9 Undecanitrogen

The  $C_s$  isomer (36) containing two pentazole ring systems in Scheme 11 was calculated to be  $180 \text{ kJ mol}^{-1}$  lower in energy than the  $C_2$  isomer (37) and  $312 \text{ kJ mol}^{-1}$  lower than the open-chain  $C_{2v}$  isomer (38). For the decomposition of the  $C_{2v}$  open-chain undecanitrogen (38) a dissociation barrier of  $59 \text{ kJ mol}^{-1}$  to open-chain  $N_9$  (31) and  $N_2$  was calculated.<sup>34</sup> As remarked for the dissociation barrier of nonanitrogen, this activation barrier for the decomposition of (38) also seems to be too high.

The open-chain  $N_{11}^+$  cation (40) in Scheme 12 is  $30 \text{ kJ mol}^{-1}$  higher in energy than the pentazole derivative (39), which is the lowest energy  $N_{11}^+$  structure reported.

**Scheme 11** Connectivity of calculated  $N_{11}$  isomers**Scheme 12** Connectivity of calculated  $N_{11}^+$  isomers

For  $N_{11}^-$ , an open-chain global minimum structure with the connectivity of (40) was reported.<sup>35</sup>

#### 4.10 Dodecanitrogen

Several minima have been found on the  $N_{12}$  energy hypersurface (see Scheme 13).<sup>36</sup> The azobispentazole  $C_{2h}$  structure (41) is the global minimum structure. It has an activation energy of  $17 \text{ kJ mol}^{-1}$  for the decomposition to the  $N_{10}$  pentazole isomer (35) and dinitrogen.<sup>37</sup> The  $C_s$  pentazole derivative (42) decomposes to open-chain  $N_{10}$  (34) and  $N_2$  with an activation energy of  $39 \text{ kJ mol}^{-1}$  and the open-chain  $C_{2h}$   $N_{12}$  (43) decomposes to the open-chain  $N_{10}$  (34) and dinitrogen with an activation energy of  $61 \text{ kJ mol}^{-1}$ . Further reported  $N_{12}$  isomers have activation energies of less than  $5 \text{ kJ mol}^{-1}$ . The azobistetrazolate dianion, where one nitrogen atom of each pentazole ring of (41) is formally exchanged with  $C^-$ , is a remarkably stable species that is used in high-energy materials.<sup>38</sup>

Higher polynitrogen species have also been calculated, but only at lower levels of theory because of computational cost. As was discussed above for the hexanitrogen isomers, the results of the calculation on polynitrogen energy hypersurfaces are heavily dependant on the method employed and the basis set used. Lower level calculations of the structures and properties of polynitrogen species have not given accurate results in the past. Therefore, polynitrogen species larger than dodecanitrogen are not discussed here.

**Scheme 13** Connectivity of calculated  $N_{12}$  isomers**Table 8** Binary compounds of nitrogen and hydrogen

## 5 BINARY COMPOUNDS OF NITROGEN AND HYDROGEN

Nitrogen forms several binary compounds with hydrogen (see Table 8). A review of binary nitrogen–hydrogen compounds can be found in the literature.<sup>39,40</sup> Substitution of hydrogen atoms by organic substituents leads to organic derivatives that are often more stable than the binary nitrogen–hydrogen compounds. Ammonia, hydrazine, diazene (diimine), hydrazoic acid, and tetrazene have been isolated so far. Ammonia and hydrazine also form salts with hydrazoic acid, that is, ammonium azide and hydrazinium azide. Hydrazinium azide forms an adduct with another hydrazine molecule, resulting in hydrazinium azide hydrazinate. Other binary nitrogen compounds, which have not been isolated but have been detected experimentally include nitrene, triazane, *cyclo*-triazane, tetrazane, and triazene. Hydrogenpentazole is discussed in Section 4.3.2.

### 5.1 Ammonia

Ammonia is a colorless, diamagnetic gas with a characteristic, penetrating odor that is irritating to the eyes and mucous membranes at concentrations higher than 100 ppm. At higher concentrations, ammonia paralyzes the breathing organs which may be fatal.<sup>4,40</sup> Some physical properties of ammonia are given in Table 9.

The ammonia molecule has a pyramidal structure (see (26)) with  $C_{3v}$  symmetry ( $d(N-H)$  101.1 pm,  $\angle(H-N-H)$  106.18°). Solid ammonia crystallizes in a distorted cubic close packed structure, where every nitrogen atom is surrounded by six other nitrogen atoms with N–N distances of 338 pm, thus every nitrogen atom is involved in six hydrogen bonds. Upon melting, about 27% of the hydrogen bonds are broken. Another 7% are broken while heating to the boiling point (see Table 10). The high vaporization enthalpy is the result of breaking the remaining hydrogen bonds, and it allows the use of ammonia as a refrigerant. Ammonia shows anomalies in its melting and boiling point as well as in the enthalpies of fusion and vaporization compared to the heavier homologues  $PH_3$ ,  $AsH_3$ ,  $SbH_3$ , and  $BiH_3$ . As for  $H_2O$  and  $HF$ , which show similar anomalies in their periodic group, these anomalies are explained by hydrogen bonding.

The ammonia molecule can undergo inversion of configuration with a planar transition state (activation energy

**Table 10** Characteristics of ammonia

|                              | Triple point | Critical point | Boiling point            |
|------------------------------|--------------|----------------|--------------------------|
| $T$ [K]                      | 195.44       | 405.4          | 239.72                   |
| $p$ [MPa]                    | 6.077        | 11.35          | 0.1013                   |
| $\rho$ [g cm <sup>-3</sup> ] | 0.2362       | 0.235          | 0.682(l)<br>0.000888 (g) |

24.5 kJ mol<sup>-1</sup>).

The observed microwave frequency of  $2.387 \times 10^{10} \text{ s}^{-1}$  for the inversion of ammonia is higher than the frequency calculated from the inversion barrier. The reason is quantum chemical tunneling through the inversion barrier. Because tunneling is proportional to the weight of the atoms, the inversion of ND<sub>3</sub> with the heavier deuterium atoms has a frequency of  $1.591 \times 10^9 \text{ s}^{-1}$ , roughly 1/15 of the frequency of ammonia. Derivatives of ammonia are also subject to this inversion with higher or lower activation energies depending on the substituent. Highly electronegative substituents increase the inversion barrier (250 kJ mol<sup>-1</sup> in NF<sub>3</sub>),  $\pi$ -bonding of the nitrogen lone pair to the substituent decreases the activation barrier (5.6 kJ mol<sup>-1</sup> in H<sub>2</sub>NCN).

Ammonia is stable at ambient conditions, but decomposes to the elements in the presence of catalysts at higher temperatures ( $\Delta H = 92.28 \text{ kJ mol}^{-1}$ ). This decomposition also takes place under UV irradiation or in electric discharges.

In the presence of catalysts, ammonia reacts with oxygen to form nitrogen oxide at relatively low temperatures of 500–700 K ( $\Delta H = -906.1 \text{ kJ mol}^{-1}$ ).

This reaction is used for the synthesis of nitric acid in the Ostwald process (see Section 7.8.1). Without catalysts, and at higher temperatures, ammonia burns in an oxygen atmosphere with a pale yellow flame forming the thermodynamically favorable products dinitrogen and water ( $\Delta H = -1267 \text{ kJ mol}^{-1}$ ). At high pressures, mixtures of ammonia and oxygen are explosive.

Strong oxidants like H<sub>2</sub>O<sub>2</sub>, KMnO<sub>4</sub>, HOCl, HNO<sub>2</sub>, or Cl<sub>2</sub> oxidize ammonia to dinitrogen ( $E^\circ = 0.27 \text{ V}$  at pH 1, see Scheme 26).

If chlorine is passed through a concentrated solution of ammonia or through ammonia gas, ammonia starts to burn and dinitrogen and HCl are formed.

The reaction of dilute chlorine with dilute ammonia yields chloramine, which can, under the right conditions, react with excess ammonia to form hydrazine (see Section 5.2.1). Fluorine reacts more vigorously than chlorine with ammonia. Bromine shows about the same reactivity and iodine reacts less vigorously. Ammonia reacts with phosphorus to form PH<sub>3</sub> and N<sub>2</sub> (see **Phosphorus–Nitrogen Compounds**), with sulfur to form H<sub>2</sub>S and S<sub>4</sub>N<sub>4</sub> (see **Sulfur–Nitrogen Compounds**) and with red-hot carbon to form NH<sub>4</sub>CN and H<sub>2</sub> (see **Carbon: Inorganic Chemistry**).

Ammonia and all other amines, NR<sub>3</sub>, are bases. A solution of ammonia in water is mildly alkaline ( $\text{p}K_{\text{b}} = 4.75$ ). Ammonia dissolves readily in water (1.176 m<sup>3</sup> at 273 K, 0.702 m<sup>3</sup> at 298 K in 1 L of water) under evolution of heat ( $\Delta H = -37.1 \text{ kJ mol}^{-1}$ ). Hydrogen bonds are formed between water and ammonia. Two hydrogen-bonded ammonium hydrates have been isolated, NH<sub>3</sub>·H<sub>2</sub>O (m.p. 194.15 K) and 2NH<sub>3</sub>·H<sub>2</sub>O (m.p. 194.32 K). In the solid state, both compounds have a three-dimensional extended hydrogen bond network.

The equilibrium (32) lies to the left side, a 0.1 mol L<sup>-1</sup> solution of ammonia in water is less than 1% dissociated into ions. The undissociated ammonia forms hydrogen-bonded hydrates NH<sub>3</sub>·xH<sub>2</sub>O. For comparison, a potassium hydroxide solution is dissociated quantitatively. Ammonium hydroxide NH<sub>4</sub><sup>+</sup> OH<sup>-</sup> is only found dissociated in solution, the undissociated form does not exist. Addition of stronger acids than water, for example, hydrochloric acid, sulfuric acid, or nitric acid, shifts the equilibrium (32) to the right side, that is, the side of the salts. The reaction of ammonia with hydrochloric acid vapors forms a white nebula in humid air, and white smoke in dry air.

Heating of the ammonium salts shifts the formation equilibrium to the ammonia side, the ammonium salts sublime under dissociation. Ammonium salts with oxidizing anions (NO<sub>2</sub><sup>-</sup>, NO<sub>3</sub><sup>-</sup>, Cr<sub>2</sub>O<sub>7</sub><sup>2-</sup>) decompose under oxidation of the ammonium nitrogen to N<sub>2</sub> or N<sub>2</sub>O.

Ammonia also has a low acidity (34) and a very slight oxidizing character (35).

Step-by-step replacement of the hydrogen atoms in ammonia with metal atoms according to (34) or (35) leads to the amides MNH<sub>2</sub>, the imides M<sub>2</sub>NH, and the nitrides M<sub>3</sub>N. The alkali and alkaline-earth amides can be obtained from the reaction of the hot metals with ammonia.

Imides are formed during heating of the amides, further heating results in the nitrides.

The alkali and alkaline-earth amides, imides, and nitrides are immediately decomposed by water to ammonia and the metal hydroxides.

Ammonia and its organic,  $H_2NR$ ,  $HNR_2$ , and  $NR_3$ , derivatives have a lone pair and can act as Lewis bases. The trialkylated derivatives of ammonia form the well-known trialkylammonium oxides  $R_3NO$  with the Lewis acid oxygen. Ammonia oxide  $H_3NO$  is less stable than the alkylated compounds, it rearranges to the more stable hydroxylamine  $NH_2OH$ . Two  $H_3NO^+$  species have been identified mass spectrometrically.<sup>41</sup> Neutralization of the ion beam and subsequent reionization of the  $H_3NO^+$  cations have shown that the neutral ammonia oxide  $H_3NO$  also has an inherent stability.

Lewis acids like boron trifluoride form Lewis acid–Lewis base complexes such as  $H_3N \cdot BF_3$  with ammonia. Ammonia also forms metal complexes, the aminocomplexes (*see Ammonia & N-donor Ligands*).<sup>42</sup> Deprotonation leads to amido, imido, and nitridocomplexes (see Scheme 14).

The nitrogen lone pair can be included in the metal–nitrogen bonds, decreasing the bond length and increasing the bond angle at the nitrogen atom.

### 5.1.1 Production of Ammonia

Ammonia is the second largest synthetic chemical product by mass and the largest by molar units.<sup>5</sup> Almost all the world consumption is manufactured from the elements nitrogen and hydrogen in a catalytic process originally developed by Fritz Haber and Carl Bosch using a promoted iron catalyst discovered by Alwin Mittasch. This process has remained largely unchanged since its discovery. A hydrogen–nitrogen mixture reacts over the iron catalyst at an elevated temperature

in the range of 673–773 K and pressures above 10 MPa ( $\Delta H = -46.22 \text{ kJ mol}^{-1}$ ). The unreacted portion of the synthesis gas is recycled and the ammonia product separated under high pressure.

Even though this reaction is exothermic, the dinitrogen molecule, which has a very high dissociation energy of  $945.33 \text{ kJ mol}^{-1}$ , has to be activated. A purely thermal activation would require temperatures well above 800–1200 K under the most favorable conditions to achieve measurable reaction rates. However, at such high temperatures and industrially reasonable pressures, the theoretically possible ammonia yield is extremely small because of the unfavorable position of the thermodynamic equilibrium. At pressures above 200 MPa, the synthesis of ammonia proceeds even in the absence of specific catalysts, here the vessel walls appear to catalyze the formation of ammonia. Electrical energy or ionizing radiation, so-called plasma processes, can also be employed to provide the activation energy. The principal difficulty is that a great part of the supplied energy is transformed either into heat, which is undesirable, or unusable incidental radiation.

In the catalytic combination of nitrogen and hydrogen, the molecules lose their translational degrees of freedom by fixation on the catalyst surface. This drastically reduces the required energy of activation. The reaction may then proceed in the temperature range 520–670 K. Electron donor–acceptor complexes allow the synthesis of ammonia at room temperature with a measurable reaction rate. Since the beginning of commercial ammonia synthesis, iron catalysts that are composed in an unreduced form of iron oxides (mainly magnetite) and a few percent of Al, Ca, and K, are generally used. Other elements such as Mg and Si may also be present in small amounts. The catalysts are usually activated in situ by reduction with synthesis gas. The added elements perform different functions. Structural stabilizers like  $Al_2O_3$  produce high inner surfaces during reduction and stabilize it under thermal stress by restraining iron crystallite growth.

**Scheme 14** Connectivity of amido, imido, and nitridocomplexes (R = H or organyl substituent)

Electronic promoters, for example, the alkali oxides, enhance the specific activity of iron–alumina catalysts. However, they reduce the inner surface or lower the thermal stability and the resistance to oxygen-containing catalyst poisons. Promoter oxides that are reduced to the metal during the activation process, and form an alloy with the iron, are a special group in which cobalt is an example that is in industrial use. Oxygen-containing compounds such as  $\text{H}_2\text{O}$ ,  $\text{CO}$ ,  $\text{CO}_2$ , and  $\text{O}_2$  only temporarily poison the iron catalysts in low concentrations. Sulfur, phosphorus, arsenic, and chlorine compounds poison the catalyst permanently.

Ruthenium on a graphite or basic oxide support is also used as a catalyst in industrial synthesis. A Co–Mo–N system has also been investigated as a potential catalytic material, however, it has to be improved to compete with the already available catalysts.<sup>43</sup>

The mechanism of the ammonia synthesis by the Haber–Bosch process includes the following steps:

1. transport of the reactants by diffusion and convection out of the bulk gas stream, through a laminar boundary layer, to the outer surface of the catalyst particles, and further through the pore system to the inner surface;
2. adsorption on the inner surface;
3. reaction of the adsorbed species, if necessary with participation by hydrogen from the gas phase, to form activated intermediate compounds;
4. desorption of the formed ammonia into the gas phase;
5. transport of the ammonia through the pore system and the laminar boundary layer into the bulk gas stream.

The nitrogen adsorption and dissociation is the rate-determining step for the intrinsic reaction for iron catalysts. The mechanism of the catalytic reaction includes adsorption of dinitrogen in the molecular state followed by chemisorption in the atomic state. Hydrogen has a direct transition from the gaseous  $\text{H}_2$  molecule into the chemisorbed atoms. The chemisorbed nitrogen atoms are then stepwise hydrogenated via  $\text{N}$ ,  $\text{NH}$ ,  $\text{NH}_2$  species to  $\text{NH}_3$ . After the ammonia synthesis, ammonia is recovered from the synthesis loop by cooling the synthesis gas to condense the ammonia under synthesis pressure. The liquid ammonia product is separated from the gas, which is again fed into the synthesis loop.

Industrial ammonia production contains the following steps:

1. Synthesis gas production
  - (a) Feedstock pretreatment and gas generation
  - (b) Carbon monoxide conversion
  - (c) Gas purification
2. Compression
3. Synthesis and purge gas management

Over the years, the most fundamental changes were made in the synthesis gas production and gas compression. These steps still have the highest potential for improvement. Some

progress has been made in the synthesis section, especially in converter design and optimization of heat recovery.

The goal of synthesis gas production is a pure mixture of nitrogen and hydrogen in the stoichiometric ratio of 1:3. The raw materials are water, air, and a carbon-containing reducing medium that may contain hydrogen (natural gas,  $\text{CH}_4$ , naphtha, petroleum) and nitrogen. Normally natural gas and sometimes naphtha is used as a reducing medium. Depending on special economic circumstances, other media are used, for example, coal, which is used for most of the ammonia production in China. The capital cost and the specific energy requirement (i.e. feed and fuel) largely depend on the raw material employed. Both are lowest for natural gas. The term feedstock is often applied to the total consumption of fossil fuel, although strictly speaking a distinction should be made between gasification feed and fuel for energy generation. The chemical reaction of hydrocarbons with water, oxygen, air, or any combination of these is generally referred to as gasification. It produces a gas mixture of  $\text{CO}$  and  $\text{H}_2$  in various proportions along with carbon dioxide and, where air is used, some nitrogen. Any carbon-containing feedstock reacts according to (40) ( $\Delta H > 0$ ) or (41) ( $\Delta H < 0$ ) or both simultaneously.

Light hydrocarbons from natural gas (methane) to naphtha (max.  $\text{C}_{11}$ ) are reacted with steam over a catalyst according to (40), a process usually called steam reforming. In (40), the proportion of hydrogen supplied by the feedstock increases with its hydrogen content with a theoretical maximum of 66% for methane. The higher bond energy of a hydrogen–oxygen bond compared to a carbon–hydrogen bond decreases the positive reaction enthalpy of (40) with increasing hydrogen content. Natural gas consists predominantly of methane and is therefore the most hydrogen-rich and energetically the best raw material for the steam-reforming route. In the partial-oxidation route, less hydrogen is produced in the primary gasification step and the raw synthesis gas has a rather high  $\text{CO}$  content. The catalytic steam-reforming technology can only be applied to light hydrocarbon feedstock (up to naphtha) but not for heavy hydrocarbons such as fuel oil or vacuum residue. These materials contain a substantial amount of sulfur and also minor quantities of heavy metals, which would poison the sensitive reforming catalyst, thus heavy feedstocks are processed by partial oxidation.

In the steam-reforming process, any sulfur compounds present in the hydrocarbon feedstock have to be removed because the nickel-containing catalysts are sensitive to poisons. This is either achieved by hydrodesulfurization (*see Hydrodesulfurization & Hydrodenitrogenation*), generally with a combination of cobalt–molybdenum and zinc oxide

catalysts, or by adsorption on activated carbon when the feed is natural gas with a rather low sulfur content.

The primary reformer consists of a multitude of reformer tubes loaded with the nickel catalyst (15–25% NiO on aluminum oxide, calcium aluminate, or magnesium aluminum spinel support) in a furnace box, in which the heat needed for the reaction is transferred to the tubes by radiation. The heat is generated in burners, generally gas-fired in the furnace box.

While only light hydrocarbons can be used for the steam-reforming process, all carbon-containing feedstocks can be processed in a noncatalytic reaction with oxygen according to (41), which is referred to as partial oxidation or coal gasification for coal feedstocks. A minor amount of water is added for process reasons and gives rise to a simultaneous reaction according to (40).

For the exothermic reaction no external heat supply is necessary.

As the synthesis of ammonia needs only nitrogen and hydrogen, all carbon oxides must be removed from the raw synthesis gas of the gasification process. Depending on feedstock and process technology, this gas contains 10–50% carbon monoxide and also varying amounts of carbon dioxide. In the water gas shift reaction, traditionally known as carbon monoxide shift conversion, the carbon monoxide serves as a reducing agent for water, to yield hydrogen and carbon dioxide ( $\Delta H = -41 \text{ kJ mol}^{-1}$ ). In this way, not only is the carbon monoxide converted to readily removable carbon dioxide but also additional hydrogen is produced:

This reaction is without volume change and is therefore independent of pressure. As an exothermic process, it is favored by lower temperatures, which shift the equilibrium to the right side. Even with a low excess of steam in the gas, the equilibrium concentrations of CO are low, for example, 0.2 vol% at 220 °C and 0.12 vol% at 200 °C for a steam/gas ratio of 0.4. The heat formed in the reaction has to be removed to keep the temperature low, and effective catalysts have to be applied to achieve a sufficient reaction rate. The process is therefore performed in steps. Heat is removed between the individual catalyst beds in which the reaction runs adiabatically. Quasi-isothermal reactors with cooling tubes through the catalyst layers are used. The process configuration and catalysts of steam reforming and partial oxidation are somewhat different. The raw synthesis gases from the partial oxidation of heavy hydrocarbons and coal differ mainly in two aspects from that produced from light hydrocarbons by steam reforming. First, depending on the feedstock composition, the gas may contain a rather high amount of sulfur compounds (mainly  $\text{H}_2\text{S}$  with smaller quantities of COS); second, the CO content is much higher, in some cases in excess of 50%. The high initial carbon monoxide concentration means that the reaction has to be performed in steps with intermediate cooling. In steam-reforming plants, the

gas from the secondary reformer enters the high-temperature shift reactor loaded with an iron–chromium catalyst at 600–630 K. After a temperature increase of around 50–70 K, depending on the initial CO concentration, the process gas has a residual CO content of around 3%. It is then cooled to 470–480 K for the low-temperature shift, which is carried out on a copper–zinc–alumina catalyst in a downstream reaction vessel and achieves a carbon monoxide concentration of 0.1–0.3 vol%.

After shift conversion, carbon dioxide, residual carbon monoxide, and sulfur compounds (only present in the synthesis gas from partial oxidation) have to be removed as they are not only a useless ballast but, more importantly, can poison the ammonia synthesis catalyst.

$\text{CO}_2$  is removed by scrubbing the synthesis gas under pressure with a solvent capable of dissolving carbon dioxide in sufficient quantity and at a sufficient rate, usually in countercurrent in a column equipped with trays or packings. The  $\text{CO}_2$  saturated solvent is flashed, often in steps, to around atmospheric pressure, and the spent scrubbing liquid is subsequently heated and regenerated in a stripping column before being recycled to the pressurized absorption column. Today, physical or chemical solvents are used. In physical solvents, carbon dioxide dissolves without forming a chemical compound, allowing a recovery by flashing. In chemical solvents, carbon dioxide becomes fixed as a chemical compound. Heat is needed for its decomposition. In the first ammonia plants, water was used for scrubbing. Today ethyl or diethyl amine as well as potassium carbonate solutions are used. As the acidic gases  $\text{CO}_2$  and  $\text{H}_2\text{S}$  are both soluble in the solvents applied, special process configurations are required to recover a separate pure  $\text{CO}_2$  fraction and an  $\text{H}_2\text{S}$ -rich fraction suitable for sulfur disposal from partial-oxidation gases.

After this bulk removal of the carbon oxides, the typical synthesis gas still contains 0.2–0.5 vol% CO and 0.005–0.2 vol%  $\text{CO}_2$ . All oxygen-containing compounds have to be reduced to a very low ppm level, as they are poisonous toward the ammonia synthesis catalysts. Methanation is the simplest method to reduce the concentrations of the carbon oxides well below 10 ppm, and is widely used in steam-reforming plants.

The advantages of simplicity and low cost more than outweigh the disadvantages of hydrogen consumption and production of additional inert gases in the makeup gas to the synthesis loop. Water is absorbed on molecular sieves. Other final purification methods are pressure-swing adsorption, or washing with liquid nitrogen.

Of the world energy consumption, 1.6% is used for the production of ammonia. In 2000, 108 megatons of ammonia were produced. About 85% is used for fertilizer production as urea, which accounts for 40% of the fertilizer production, and

ammonium nitrate, phosphate, and sulfate. Ammonia is also used as a solvent, for the nitriding of steel, and as a refrigerant, due to its low boiling point and high heat of evaporation.

### 5.1.2 Ammonia as a Solvent

Ammonia possesses similar physical properties to that of water, which is similarly highly associated.<sup>44</sup> It is a good solvent for many compounds. Owing to the lower dielectric constant ( $\text{NH}_3$ : 16.9,  $\text{H}_2\text{O}$ : 78.3 at 298 K) of ammonia in comparison with water, less polar compounds are more soluble in ammonia and polar compounds, for example, salts, are more soluble in water. Organic compounds tend to have a higher solubility in ammonia than in water. Ammonium salts, nitrates, nitrites, cyanides, and thiocyanates dissolve readily in ammonia. The solubility increases from fluorides to chlorides, bromides, and iodides. Salts with higher charged ions dissolve only poorly in ammonia. This results in the reversal of some precipitation reactions in ammonia compared to water.

As a hard base, water prefers to coordinate to the harder acid  $\text{Ba}^{2+}$ , the softer base ammonia prefers to coordinate the softer acid  $\text{Ag}^+$  to form  $\text{Ba}(\text{OH}_2)_n^{2+}$  and  $\text{Ag}(\text{NH}_3)_2^+$ , respectively. Sulfates, sulfites, carbonates, phosphates, arsenates, oxides, and sulfides are virtually insoluble in ammonia. Hydroxides and amides are also very poorly soluble.

In ammonia, the  $\text{NH}_4^+$  ion is the strongest available acid and the  $\text{NH}_2^-$  ion the strongest available base. Compounds of the type  $\text{HX}$  that produce  $\text{NH}_4^+$  ions are acids in this system,  $\text{MR}$  compounds such as  $\text{LiCH}_3$  or  $\text{NaSiH}_3$  are bases as they produce  $\text{NH}_2^-$  ions.

Ammonia is an attractive solvent if strong bases are required, since  $\text{NH}_2^-$  is more basic than  $\text{OH}^-$ , but is less useful for reactions requiring strong acids. Acids like acetic acid that are weak acids in water are strong acids in ammonia and dissociate fully to form ammonium ions. Strong bases like  $\text{C}\equiv\text{C}^{2-}$ ,

$\text{Ph}_3\text{Ge}^-$ , or  $\text{R}_2\text{P}^-$ , that are immediately hydrolyzed in water, can be handled in ammonia. Complexation is an important factor for the solution of metal salts in ammonia.  $\text{Zn}(\text{NH}_2)_2$ , which is insoluble in ammonia, is like the hydroxocomplex  $\text{Zn}(\text{OH})_2$ , which is insoluble in water, amphoteric. It dissolves in acidic solution to form  $\text{Zn}(\text{NH}_3)_4^{2+}$  or in basic solution to form  $\text{Zn}(\text{NH}_2)_4^{2-}$ .

Elements that are above  $\text{H}_2/\text{H}^+$  are oxidized under evolution of dihydrogen, elements below  $\text{NH}_3/\text{N}_2$  are reduced under evolution of dinitrogen (see Table 11). This leaves a range of only +0.04 V in which oxidizing agents more powerful than  $\text{N}_2$ , and reducing agents more powerful than  $\text{H}_2$  are thermodynamically stable. However, kinetic effects leading to overvoltages of  $\text{H}_2$  and  $\text{N}_2$  extend the range from +1.0 V to -1.0 V in basic solution and from -2.05 V to +0.6 V in acidic solution. Therefore, even strong reductants like  $[\text{M}^0(\text{CN})]^{4-}$  ( $\text{M} = \text{Ni}, \text{Pd}, \text{Pt}$ ) and strong oxidizers like  $\text{O}_2^-$  or  $\text{O}_3^-$  can be handled in liquid ammonia.

Alkali and alkaline-earth metals dissolve in ammonia, in contrast to water, without the evolution of dihydrogen, forming intensely colored solutions that are strong reducing agents. The solutions, which have lower densities than ammonia, are metastable in the absence of water and dioxygen. Over time, or in the presence of catalysts such as  $\text{FeCl}_2$ , these solutions decompose to the metal amides and dihydrogen. Beryllium and magnesium do not dissolve because metal ionization and lattice energies are too high, but solutions of these metals in ammonia can be prepared by the electrochemical reduction of solutions of their salts in ammonia. The color of the solutions depends on concentration; dilute solution are intense blue and salt-like, concentrated solutions bronze-gold and truly metallic. At intermediate concentrations, there is a concentration-dependent metal-nonmetal transition, which is associated with a remarkable liquid-liquid phase transition and unusual critical properties. In one mol of ammonia, the following amounts of metals are dissolved at 223 K: Li 0.27 mol, Na 0.19 mol, K 0.20 mol, Rb 0.3 mol, Cs 0.43 mol.

Saturated solutions of lithium in ammonia have the lowest density ( $\rho = 0.48 \text{ g cm}^{-3}$ ) of any known liquid at room temperature and provide the lowest-temperature liquid metals with a deep pseudoeutectic extending to 88 K.<sup>45</sup> Dissolution of lithium atoms in ammonia produces a rich variety of solvated electronic and ionic species. At very low concentrations ( $c < 0.01$  mole percent metal, MPM),

**Table 11** Standard potentials in liquid ammonia compared to standard potentials in liquid water in parentheses

the solutions are essentially electrolytic, and contain solvated ions and isolated electrons. The latter are localized within polaronic solvent cavities with an approximate radius of 3 Å, causing the decrease in density of the metal solutions compared to ammonia and the paramagnetism of the solutions. At intermediate concentrations (0.01 MPM to 2 MPM), the electronic and magnetic properties are dominated by spinpaired species, for example, peanut-shaped bipolarons. These species account for about 90% of the excess electrons at 1 MPM. A metal–nonmetal transition takes place at around 4 MPM, with the onset of liquid–liquid phase separation below 210 K. At higher concentrations, the excess electronic states become more extended and itinerant, forming solutions that are good metals. Saturated solutions of lithium in ammonia have a concentration of 22 MPM, and an electrical conductivity that exceeds that of liquid mercury. The lithium cations are strongly solvated by four ammonia molecules, forming  $\text{Li}(\text{NH}_3)_4^+$ . This suggests that the excess electrons are almost fully dissociated from lithium and trapped in polaronic cavities formed by free-solvent molecules. The nonmetal-to-metal transition is explained as the lack of enough free-solvent molecules to fully solvate all excess electrons and the resulting overlap of the solvation shells of different electrons. The alkaline-earth metal solutions in ammonia contain hexacoordinated cations  $\text{M}(\text{NH}_3)_6^{2+}$ .

### 5.1.3 Ammonium Salts

The ammonium ion  $\text{NH}_4^+$  has a tetrahedral structure and is slightly acidic ( $\text{p}K_a = 9.25$ ). If no strong hydrogen bonds are present, like in  $\text{NH}_4\text{F}$ , the properties of ammonium salts, for example, the solubility and the structure, are similar to the corresponding potassium and rubidium salts. The reasons are similar ionic radii of the ammonium (143 pm), potassium (137 pm), and rubidium ions (148 pm). The oxonium salts  $\text{H}_3\text{O}^+\text{X}^-$ , which have lower melting points, are also similar to the ammonium salts. The similar properties of element-hydrogen compounds have been rationalized by the hydride displacement law shown in Table 12.

Accordingly, the isoelectronic  $\text{FH}_2$ ,  $\text{OH}_3$ ,  $\text{NH}_4$ , as well as Na form cations, for example, in  $\text{Na}^+\text{ClO}_4^-$ ,  $\text{FH}_2^+\text{ClO}_4^-$ ,  $\text{OH}_3^+\text{ClO}_4^-$ , and  $\text{NH}_4^+\text{ClO}_4^-$ . NeH has only been observed in the gas phase. The saturated molecules HF,  $\text{H}_2\text{O}$ ,  $\text{NH}_3$ , and  $\text{CH}_4$  correspond to the noble gas neon and OH,  $\text{NH}_2$ , and  $\text{CH}_3$  are found either single bonded or anionic like the fluorine atom. Examples are the ionic compounds  $\text{Na}^+\text{F}^-$ ,

**Table 12** Hydride displacement law

| C | N  | O                     | F                                        | Ne                                                          | Na                                                           |
|---|----|-----------------------|------------------------------------------|-------------------------------------------------------------|--------------------------------------------------------------|
|   | CH | NH<br>CH <sub>2</sub> | OH<br>NH <sub>2</sub><br>CH <sub>3</sub> | FH<br>OH <sub>2</sub><br>NH <sub>3</sub><br>CH <sub>4</sub> | NeH<br>FH <sub>2</sub><br>OH <sub>3</sub><br>NH <sub>4</sub> |

$\text{Na}^+\text{OH}^-$ ,  $\text{Na}^+\text{NH}_2^-$ ,  $\text{Na}^+\text{CH}_3^-$  or the covalent compounds  $\text{CH}_3\text{F}$ ,  $\text{CH}_3\text{OH}$ ,  $\text{CH}_3\text{NH}_2$ , and  $\text{CH}_3\text{CH}_3$ . The ammonium radical  $\text{NH}_4^\bullet$ , which is isosteric to the alkali metals, has so far not been isolated.

Ammonium ions can coordinate up to four ammonia molecules via hydrogen bonds, for example,  $\text{NH}_4\text{I} \cdot 4\text{NH}_3$  (m.p. 268). The ionic, hydrogen-bonded structure  $\text{NH}_4 \cdots \text{X}$  shifts to an adduct structure  $\text{NH}_3 \cdots \text{HX}$  with weaker acids HX. For an explanation of hydrogen bonds, see *Hydrogen Bonding & Dihydrogen Bonding*. Some properties of important ammonium salts are given in Table 13.

**Ammonium Chloride.** Ammonium chloride, which occurs naturally in volcanic material, forms two solid phases. The  $\alpha$ -modification (cubic, CsCl type), which is stable at room temperature, changes reversibly to the  $\beta$ -modification (cubic, NaCl type) at 457.6 K. The slightly hygroscopic ammonium chloride sublimates easily, the dissociation to ammonia and HCl is complete at 520 K. It is very soluble in water.<sup>5</sup>

Ammonium chloride is produced in a modified Solvay process, which is used for the production of sodium carbonate.

If HCl is available cheaply, ammonium chloride can also be produced from ammonia and HCl. Ammonium chloride as gas, solid, or in solution is corrosive because it is acidic, it complexes metal ions and it contains the corrosive chloride ion.

The 150 kilotons of ammonium chloride that are produced per year are mostly used as fertilizer and, in order of importance, for solid electrolytes in dry cell batteries, a component of quarrying explosives, hardeners for formaldehyde-based adhesives, one component of etching solutions in the manufacture of printed circuit boards, and a component, along with zinc chloride, of fluxes in tin and zinc plating.

**Table 13** Properties of important ammonium salts

|                                            | $\text{NH}_4\text{Cl}$ | $(\text{NH}_4)_2\text{SO}_4$ | $\text{NH}_4\text{NO}_3$ | $\text{NH}_4\text{HCO}_3$ |
|--------------------------------------------|------------------------|------------------------------|--------------------------|---------------------------|
| m.p. [K]                                   | dissoc. 520            | decomp. > 575                | 442.8                    | decomp. 309–333           |
| $\Delta H_f$ [kJ mol <sup>-1</sup> ]       | −314.6                 | −1180.9                      | −365.1                   | −849                      |
| $\rho$ [g cm <sup>-3</sup> ]               | 1.530                  | 1.77                         | 1.725                    | 1.58                      |
| $C_p$ [J g <sup>-1</sup> K <sup>-1</sup> ] | 1.63                   | 1.423                        | 1.70                     | 1.53                      |

**Ammonium Sulfate.** The colorless, crystalline ammonium sulfate cannot be melted at atmospheric pressure without decomposition at 508 K, releasing ammonia and forming  $\text{NH}_4\text{HSO}_4$ . After cleavage of water, ammonium bisulfate  $(\text{NH}_4)_2\text{S}_2\text{O}_7$  is left. However, the ammonia vapor pressure of pure, anhydrous ammonium sulfate is effectively zero up to 350 K. Above 573 K, decomposition yields  $\text{N}_2$ ,  $\text{SO}_2$ ,  $\text{SO}_3$ , and  $\text{H}_2\text{O}$  in addition to ammonia.<sup>5</sup>

Ammonium sulfate is synthesized from ammonia, which stems from either coke oven gas or the Haber–Bosch process, and sulfuric acid.

Ammonium sulfate is a coproduct in the production of synthetic-fiber intermediates, such as caprolactam, acrylonitrile, and methyl methacrylate, and in the production of formic acid and acrylamide. The recovery of ammonium sulfate from these syntheses has gained importance in the last thirty years. Almost all of the 2.8 megatons of ammonium sulfate produced annually is used as fertilizer. In industrial countries, ammonium sulfate is almost always a coproduct or by-product in other processes and can only be sold as fertilizer, mostly in developing countries. In these countries, its low nitrogen content makes the transportation cost per unit of nitrogen higher than for other nitrogen fertilizers.

**Ammonium Nitrate.** Ammonium nitrate is a colorless, deliquescent crystalline salt. At standard pressure, five modifications of ammonium nitrate exist (Table 14). The phase change at 305.5 K is of particular importance for the handling of ammonium nitrate fertilizer. On passing through the phase change repeatedly, granules of ammonium nitrate lose strength and finally disintegrate because of the differing densities.<sup>5</sup>

Ammonium nitrate dissolves readily in water; in addition, the salt is hygroscopic. Therefore, care must be taken to avoid moisture during transportation and storage. When the salt dissolves in water, heat is absorbed ( $\Delta H = 26 \text{ kJ mol}^{-1}$ ). Therefore, ammonium nitrate can be used in freezing mixtures, for example, in mixtures with sodium chloride and ice.

In the synthesis of ammonium nitrate from the neutralization of 45–65%  $\text{HNO}_3$  with gaseous  $\text{NH}_3$ , the considerable heat of the reaction is used for the partial or complete evaporation of the water.

**Table 14** Modifications of ammonium nitrate

| Modification  | Existence range [K] | Crystal system |
|---------------|---------------------|----------------|
| $\alpha$      | <256.2              | tetragonal     |
| $\beta$       | 305.5–256.2         | orthorhombic   |
| $\gamma$      | 357.5–305.5         | orthorhombic   |
| $\delta$      | 398.4–357.4         | tetragonal     |
| $\varepsilon$ | 442.8–398.4         | cubic          |

Depending on the reaction conditions, 95–97% solutions of ammonium nitrate can be obtained. Quick and thorough mixing of the compounds is necessary to avoid local overheating, losses of nitrogen, and decomposition of the ammonium nitrate. Ammonium nitrate has to be prevented from caking during storage by a final surface treatment (coating). The earlier practice of powdering with inorganic substances to separate the grains mechanically has mostly been replaced by treatment of the grain with effective organic surfactants, such as cationic long-chain fatty amines or anionic alkylarylsulfonates.

Ammonium nitrate undergoes several decomposition processes. At 442.8 K, ammonium nitrate starts to melt and at 443.2 K endothermic dissociation takes place ( $\Delta H = +175 \text{ kJ mol}^{-1}$ ):

On careful heating to 473 K,  $\text{N}_2\text{O}$  is eliminated ( $\Delta H = -37 \text{ kJ mol}^{-1}$ ).

Above 503 K, dinitrogen and  $\text{NO}_2$  are eliminated ( $\Delta H = -102 \text{ kJ mol}^{-1}$ ).

Further heating results in the formation of dinitrogen and dioxygen accompanied by detonation ( $\Delta H = -118.5 \text{ kJ mol}^{-1}$ ).

Hydrogen ions, chlorides, and heavy metals catalyze the decomposition of ammonium nitrate.

Pure ammonium nitrate, highly concentrated hot solutions of ammonium nitrate, various mixtures of ammonium nitrate, and ammonium nitrate fertilizer can be detonated by shock waves unless stabilized. Several times, huge amounts of ammonium nitrate have exploded, causing severe damage. One of the latest accidents happened in Toulouse in 2001, where 200 to 300 tons of ammonium nitrate exploded in a warehouse. The blast blew out windows in the city center 3 km away and created a crater with a diameter of 50 meters and more than 10 meters deep.

For safety reasons, solidified ammonium nitrate should not be broken up by blasting. Products containing ammonium nitrate must be stored separately from oxidizable and inflammable materials and, if ammonium nitrate must be heated (during production, evaporation, etc.), the quantity must be kept small and catalysts avoided. In several countries, inert materials such as limestone powder, dolomite, or precipitated calcium carbonate, are added to ammonium

nitrate for fertilizer use (calcium ammonium nitrate). Such fertilizers, containing no more than 80% ammonium nitrate, no more than 0.4% combustible constituents, and no less than 18% magnesium or calcium carbonate, are considered nondetonatable.

The 15 megatons of ammonium nitrate produced annually are used mainly as fertilizer, either pure, diluted, or in multinutrient mixtures. It is used in liquid fertilizers with urea.

Safety explosives for mining are produced from ammonium nitrate. Owing to its low explosion temperature in mixtures with NaCl, the temperature is not high enough to set off the much-feared firedamp. For greater explosive power, for example, for mining (rock explosives), porous-prilled ammonium nitrate containing approximately 6% diesel oil is used.

**Ammonium Carbonates.** In the ternary system,  $\text{NH}_4^+/\text{H}_2\text{O}/\text{CO}_2$  four compounds are found: ammonium hydrogencarbonate  $\text{NH}_4\text{HCO}_3$  ( $\rho = 2.4 \text{ g cm}^{-3}$ ), ammonium carbonate  $(\text{NH}_4)_2\text{CO}_3 \cdot \text{H}_2\text{O}$  (m.p. 316.2 K), ammonium sesquicarbonate  $(\text{NH}_4)_2\text{CO}_3 \cdot 2\text{NH}_4\text{HCO}_3 \cdot \text{H}_2\text{O}$ , and ammonium carbamate  $\text{NH}_4\text{CO}_2\text{NH}_2$  (m.p. 402 K).<sup>5</sup> Ammonium hydrogencarbonate, also called ammonium bicarbonate is the only compound soluble in water without decomposition.  $(\text{NH}_4)_2\text{CO}_3 \cdot \text{H}_2\text{O}$  is only formed under precisely defined conditions, which are difficult to achieve in production. Therefore, usually equimolar mixtures of ammonium carbamate and ammonium hydrogencarbonate are used and sold as ammonium carbonate. In the presence of air, ammonium carbonate  $(\text{NH}_4)_2\text{CO}_3$  forms ammonium bicarbonate  $\text{NH}_4\text{HCO}_3$ , which decomposes at temperatures higher than 333 K to ammonia and  $\text{CO}_2$ . Owing to this decomposition, ammonium bicarbonate is mainly used as an expanding agent for baked goods. It is also used in buffer solutions for the neutralization of acids when additional anions are undesirable. Further uses include an ammonization agent for the humic acid in turf, a nitrogen source for yeast cultures, and blowing agents for foam rubber and poly(vinyl chloride). Ammonium carbamate is used as an insecticide for cereals, a neutralization agent in the chemical industry, and as feedstock for ammonium carbonate production. Ammonium carbonate is used in the manufacture of catalysts, as a blowing agent in foam rubber and foam plastic, and as an additive in photographic developers. In a number of countries, it is also used as an expanding agent in certain baked goods.

## 5.2 Hydrazine

Hydrazine is a colorless, viscous liquid that fumes in air. A comprehensive review of the chemistry, properties, and production of hydrazine can have been produced.<sup>46</sup> The toxic substance has an odor reminiscent of ammonia and forms a hydrate  $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{O}$ . A  $2s2p^3$  hybridization of the nitrogen atoms in hydrazine leads to a tetrahedral arrangement similar to that of saturated carbon atoms, where a lone pair of electrons

replaces one ligand of the carbon atom. The repulsion of these lone pairs destabilizes the N–N single bond. Rotation of one-half of the hydrazine molecule around the N–N bond leads to three different conformations, which are shown in Scheme 15.

The unsymmetrical *gauche* conformation (**46**) is the most stable structure. The staggered (anti) chair structure (**45**) is about  $3 \text{ kJ mol}^{-1}$  higher in energy, and the eclipsed (syn) boat structure (**44**) represents a transition state that was found to be  $25\text{--}41 \text{ kJ mol}^{-1}$  higher in energy by spectroscopic and dipole measurements. The high rotation barrier compared to ethane ( $10.7\text{--}13.8 \text{ kJ mol}^{-1}$ ) was explained by the repulsion of the nitrogen lone pairs. Hydrogen peroxide (see **Oxygen: Inorganic Chemistry**) is another example of this lone pair interaction. At room temperature, hydrazine does not rotate freely in the gas phase, the  $\text{NH}_2$  groups only twist and oscillate against each other.

The bonding parameters of hydrazine as obtained by various experimental investigations are in the expected range for an  $sp^3$  hybridized nitrogen atom (see Table 15).

In liquid hydrazine, hydrogen bonding occurs between the hydrazine molecules similar to the hydrogen bonding in liquid water. In solid hydrazine, the hydrogen bonds have NH–N distances between 319 and 367 pm. In hydrazine hydrate, each hydrazine molecule is linked via six hydrogen bonds to surrounding water molecules so that the hydrazine molecules are separated from each other by water molecules.<sup>47</sup> Some physical properties of hydrazine and hydrazine hydrate are shown in Table 16.

### 5.2.1 Production of Hydrazine

For a long time, the Raschig process, which was discovered in 1907, was used for the production of hydrazine.<sup>5</sup> Here, ammonia is oxidized with sodium hypochlorite in alkaline solution ( $\text{pH} = 8\text{--}11$ ). In the initial rapid reaction, (55) sodium hypochlorite reacts with ammonia, forming chloramine. Chloramine then reacts with ammonia in a slower second reaction.<sup>5,46</sup>

Scheme 15 Rotamers of hydrazine

Table 15 Bonding parameters of hydrazine

|                            | IR             | X-ray | GED      |

Chloramine reacts preferentially with the produced hydrazine, thus limiting the stationary hydrazine concentration in solution.

To avoid this decomposition, an excess of ammonia has to be present. Transition metal ions, which are generally present as contaminants in the starting materials and the process water, catalyze this reaction and have to be removed by complexation with glue, gelatin, or albumin. One of the main disadvantages of the Raschig process is the high dilution of the obtained hydrazine (3% solution in water). To obtain hydrazine hydrate, an energy-intensive multistage distillation is necessary. The Bergbau–Bayer–Whiffen or ketazine process solves some of these disadvantages. Here a ketone, typically acetone, reacts with hydrazine forming a ketazine  $\text{Me}_2\text{C}=\text{N}=\text{N}=\text{CMe}_2$  or acetone hydrazone  $\text{Me}_2\text{C}=\text{NNH}_2$ . In contrast to hydrazine, ketazines are not oxidized by chloramine, thus improving the yield. The liberation of hydrazine from the ketazine is dependant on further use. For hydrazinium(I) sulfate, the azine is hydrolyzed with dilute sulfuric acid; for hydrazine hydrate, a high-pressure steam hydrolysis is used.

In anhydrous systems, the low hydrazine concentration is avoided.<sup>48</sup> Chlorine and ammonia can react in the gas phase to form chloramine, which then reacts with ammonia to form hydrazine. As in the Raschig process, the reaction (57) of chloramine with hydrazine limits the yields. Substituted hydrazines can be prepared using this process with the appropriate substituted amines.

In the PCUK process (introduced by Produits Chimiques Ugine Kuhlmann), ammonia is oxidized with hydrogen peroxide in the presence of a ketone. A ketazine is formed as in the ketazine process, which is then processed similarly. Ketones with many different substituents, even aldehydes,

have been examined for this reaction. Normally acetone, methylethylketone, or diethylketone are employed.

The PCUK process is used for most of the newly built hydrazine plants. Its main advantages are higher yield (close to 90% compared to 60–70% with Raschig technology) and lower energy consumption. Furthermore, no sodium chloride has to be disposed off.

The production of hydrazine from urea by treatment with sodium hypochlorite is no longer used. Here urea was oxidized with sodium hypochlorite followed by hydrolysis and decarboxylation to yield hydrazine.

Many other processes have been investigated. Attempts to synthesize hydrazine from nitrogen and hydrogen gave only traces of hydrazine. In the biological nitrogen fixation process (see *Nitrogenase Catalysis & Assembly*), hydrazine is an intermediate. The oxidation of ammonia has been investigated by photolysis,  $\gamma$ -radiolyses, glow discharge, arc plasma electrolysis, chemonuclear processes, and chemical oxidation. Also, other starting materials such as semicarbazide, nitramide, nitrosamines, nitroso compounds, and nitrogen oxides were used. These processes are not used on an industrial scale. About 74 kilotons of hydrazine hydrate were produced in 2000.

Hydrazine is mostly sold as an aqueous solution; anhydrous hydrazine is only used as a rocket fuel or as a mono- or bipropellant for satellites and spacecrafts. About 80–90% of the hydrazine produced is converted into organic derivatives. Other applications are based on its use as a reducing agent, as an energy-rich compound, or on its hydrogen storage capacity.

### 5.2.2 Anhydrous Hydrazine

All technical processes for the synthesis of hydrazine yield either hydrazine in aqueous solution or hydrazine hydrate. Most applications can use hydrazine hydrate, but for some applications, for example, rocket propulsion, anhydrous hydrazine is necessary. The water can be removed by a chemical reaction followed by distillation or by azeotropic distillation with an auxiliary fluid. As water binding chemicals, calcium carbide, sodium hydroxide, calcium oxide, calcium hydride, barium oxide, barium hydroxide, and barium pernitride  $\text{Ba}_3\text{N}_4$  have been used. The use of sodium or calcium metal and sodium amide is best avoided because of the formation of explosive hydrazides. Starting from hydrazine hydrate (64% hydrazine), sodium hydroxide is generally used

to obtain 90% hydrazine. The rest of the water can be removed by repeated treatment with barium oxide and recondensation. The separation of the drying agent and hydrazine by distillation has resulted in many explosions in the past and is, if possible, best avoided. In technical processes, hydrocarbons with similar boiling points as hydrazine, for example, *n*-heptane, are used as blanketing fluids to dilute the hydrazine vapor and prevent explosions. Upon recondensation, they are immiscible with hydrazine and are easily siphoned off. Another approach for drying hydrazine uses an entrainer, a fluid that forms an azeotrope with water, boiling at a temperature different from hydrazine or hydrazine hydrate. Aniline is ideally suited for this purpose.<sup>46</sup>

For liquid–liquid extraction, fluids that have a high affinity for hydrazine and are immiscible with water were found. Fluoroalcohols, typically  $\text{H}(\text{CF}_2)_6\text{CH}_2\text{OH}$ , are ideally suited for this purpose. Anhydrous hydrazine can also be prepared by reacting hydrazinium salts with strong bases.

The equilibrium of the reaction of hydrazinium hydrogensulfate with liquid ammonia (60) is shifted to the product side by the precipitation of  $(\text{NH}_4)_2\text{SO}_4 \cdot 3\text{NH}_3$ . Organic amines that are weaker bases than hydrazine but have higher boiling points than hydrazine can also be used for the production of anhydrous hydrazine. In a mixture with these bases, hydrazine always has a small equilibrium concentration and can be distilled off under reduced pressure. It is also possible to thermally decompose some hydrazinium salts, yielding anhydrous hydrazine. Here hydrazinium tetraborate  $(\text{N}_2\text{H}_5)_2(\text{B}_4\text{O}_7)_3$ , the hydrazinium salt of carbazic acid  $\text{N}_2\text{H}_5^+\text{H}_2\text{NNHCO}_2^-$ , and the hydrazinium salt of cyanuric acid have been used. Further purification by fractional crystallization, sublimation, or distillation at low pressure is possible.

### 5.2.3 Chemical Properties of Hydrazine

Hydrazine is an endothermic compound that decomposes at higher temperatures, sometimes explosively, to form dinitrogen and ammonia.<sup>46</sup>

Hydrazine and aqueous solutions of hydrazine are strong reducing agents. Depending on the oxidizing agent, catalysts, pH, and temperature, hydrazine can react in different ways. In aqueous solution, hydrazine can be oxidized in a one, two, or four electron oxidation to form dinitrogen, a mixture of dinitrogen and ammonia or ammonium azide.<sup>49</sup> Hydrazoic acid (63) is only formed in a highly acidic solution with strong oxidants like  $\text{H}_2\text{O}_2$ ,  $\text{ClO}_3^-$ , or  $\text{S}_2\text{O}_8^{2-}$ . The oxidation potentials are given in Table 17.

Reactions (63) and (65) often occur simultaneously. For example, iodate or iodine in acidic conditions and cyanoferrate(III) in alkaline solutions prefer reaction (62), while iron(III) or manganate prefer reaction (64). The oxidation to dinitrogen either takes place directly or stepwise in a one-electron oxidation with hydrazyl radicals  $\text{N}_2\text{H}_3\cdot$  ( $\Delta H_f = 231 \text{ kJ mol}^{-1}$ ) as intermediates.

The hydrazyl radicals either dimerize to form tetrazane, which then decomposes to form dinitrogen and ammonia (62), or are oxidized further to diazene, which disproportionates to dinitrogen and hydrazine, thus yielding (64).

Under atmospheric conditions, an autoxidation of hydrazine takes place.<sup>50</sup>

While autoxidation is undesirable during storage, it limits the environmental damage after spillage and is the driving force in hydrazine–air fuel cells, which have a standard potential of 1.56 V, which is split into 1.16 V for the oxidation of hydrazine (68) and 0.4 V for the reduction of dioxygen (69).

Hydrazinium salts do not show autoxidation. When ignited in air, hydrazine burns rapidly and completely with a high-energy release ( $\Delta H = -625.1 \text{ kJ mol}^{-1}$ ).

When hydrazine is combined with strong oxidizers ( $\text{N}_2\text{O}_4$ ,  $\text{HNO}_3$ , and  $\text{HClO}_4$ ), spontaneous ignition takes place. These hypergolic mixtures are used for rocket propulsion. The end stage of the European Ariane 5, for example, uses a bipropellant mixture of methylhydrazine and  $\text{N}_2\text{O}_4$ .<sup>51</sup>

Reaction with  $\text{CO}_2$  gives hydrazinocarboxylic acid (carbazidic acid)  $\text{H}_2\text{NNCO}_2\text{H}$  and ammonia. The reaction of hydrazine with carbon monoxide at high pressure and temperature in the presence of iron pentacarbonyl leads

**Table 17** Oxidation potentials of hydrazine

|      | pH = 0                      | pH = 14                     |
|------|-----------------------------|-----------------------------|
| (62) | $E^\circ = -1.74 \text{ V}$ | $E^\circ = -2.42 \text{ V}$ |
| (63) | $E^\circ = +0.11 \text{ V}$ | $E^\circ = -0.92 \text{ V}$ |
| (64) | $E^\circ = -0.23 \text{ V}$ | $E^\circ = -1.16 \text{ V}$ |

to semicarbazide  $\text{H}_2\text{NCONHNH}_2$ . Thiocarbonhydrazide  $\text{S}=\text{C}(\text{NHNH}_2)_2$  is prepared by reacting carbon disulfide with excess hydrazine in aqueous solution. Hydrazine also reacts with many nitrogen compounds, where it is almost always oxidized.<sup>52</sup> Nitrite, nitrite esters, and occasionally also nitrates can oxidize hydrazine to azides, which are often unwanted because of their explosive hazards. The reaction of hydrazine and its derivatives with many organic compounds are used for analytical purposes.<sup>53</sup>

Pure hydrazine undergoes an autoionization according to the following equation

with an equilibrium constant  $K = 2 \times 10^{-25}$ .

This is nine orders of magnitude less than the corresponding constant of water and eight orders of magnitude larger than the self-ionization constant of ammonia. Each nitrogen atom of hydrazine can accept one proton, thus two series of salts can be formed ( $\text{p}K_1 = 6.07$ ,  $\text{p}K_2 = 15.1$ ). With a  $\text{p}K_1$  of 6.07, hydrazine is a weaker base than ammonia. The second nitrogen atom is only protonated by strong bases like  $\text{H}_2\text{SO}_4$  or  $\text{HClO}_4$ . The diprotonated salts are not stable in aqueous solution; they hydrolyze with water acting as a base according to equation (71).

A solution of hydrazinium(2+) chloride in water is thus equivalent to a solution of hydrazinium(1+) chloride with an equimolar excess of HCl. Hydrazinium salts are similar to ammonium salts, they are colorless and crystallize well. The

difference is their lower stability due to the lower basicity of hydrazine and their reducing nature. Salts with strong oxidizing acids like nitric or perchloric acid may be explosive and require careful handling. The salts are characterized by strong hydrogen bonding between the hydrazinium ions and the anions. Some hydrazinium salts crystallize as hydrates.

Hydrazine only acts as a base with very strong bases, for example, sodium amide or sodium hydride.

Hydrazine can occupy the space commonly occupied by water in crystallization. These compounds are sometimes called hydrazinates in analogy to hydrates. This addition is reversible. Hydrazinium salts and their hydrazine adducts can be used as gas generators, for example,  $(\text{N}_2\text{H}_5)_2(\text{N}_2\text{H}_4)_2\text{C}_2\text{N}_{10}$  as they release huge amounts of gas upon decomposition.<sup>54</sup>

The two lone electron pairs of the nitrogen atoms make hydrazine a good ligand for complex formation.<sup>55</sup> One or both nitrogen atoms of hydrazine can be bound to a metal center (see **Ammonia & N-donor Ligands**). Complexes of deprotonated hydrazine are also known, thus giving hydrazine a great structural variety as shown in Scheme 16.

Hydrazine forms Lewis acid–Lewis base adducts with electron-deficient compounds, for example,  $\text{BF}_3 \cdot \text{N}_2\text{H}_4$ .

### 5.3 Triazane and Tetrazane

Triazane and *cyclo*-triazane form in the capillaries of fully  $\text{Ag}^+$ -exchanged zeolite after exposure to  $\text{NH}_3$  gas at ambient temperature. The  $\text{N}_3\text{H}_5$  molecules ( $d(\text{N}-\text{N})$  160(10) pm,  $<(\text{N}-\text{N}-\text{N})$  107(8)°) form triple bridges via the terminal

**Scheme 16** Coordination of hydrazine ligands in complexes

nitrogen atoms in the complex  $\text{Ag}(\text{N}_3\text{H}_5)_3^{2+}$ .<sup>56</sup> *Cyclo*-triazane acts as a  $\eta^3$  ligand in  $\text{Ag}(\text{N}_3\text{H}_5)^+$  ( $d(\text{N}-\text{N})$  149(8) pm). The triazane molecules are further stabilized by hydrogen bonds to the oxygen atoms of the surrounding zeolite framework. Weak  $\text{N}_3\text{H}_5^+$  and  $\text{N}_3\text{H}_4^+$  peaks were observed in the mass spectrum of the zeolite crystal. Organic derivatives of *cyclo*-triazane (triaziridine) are known, for example, *trans*-diisopropyltriaziridine.<sup>39</sup>

Triazane and tetrazane ( $\Delta H_f = 293(10) \text{ kJ mol}^{-1}$ ) were observed mass spectrometrically in a continuous-flow microwave plasma discharge excited in hydrazine gas in helium.<sup>57</sup> Tetrazane is formed from the dimerization of  $\text{N}_2\text{H}_3$  radicals and decomposes to dinitrogen and ammonia.

Otherwise the free bases have not yet been observed. In the case of triazane, only the decomposition products were observed.

Substitution of the hydrogen atom of the central nitrogen atom leads to more stable organyltriazanes  $\text{H}_2\text{NNRNH}_2$ .<sup>58</sup>

### 5.3.1 Triazanium Salts

The Raschig hydrazine synthesis can be extended one further step. Reaction of chloramine with hydrazine in ether yields triazanium chloride, which decomposes instantaneously.<sup>39</sup> This is responsible for hydrazine decomposition during the Raschig synthesis (see Section 5.2.1):

Hydroxylamine-*O*-sulfonic acid reacts with hydrazine to form a precipitate of triazanium hydrogensulfate ( $\text{H}_2\text{NNH}_2 \text{NH}_2^+ \text{HSO}_4^-$ ). Reaction of this solution with an appropriate barium salt in 0.1 M aqueous solution yielded solutions of the nitrate, perchlorate, chlorate, acetate, cyanide, bromide, and hydroxide salts.<sup>59</sup> The stability of the salts decreases in the order hydrogen sulfate > nitrate > perchlorate > chlorate > acetate > azide > cyanide > bromide > hydroxide. The stability of the solutions decreases with decreasing  $\text{H}^+$  concentration, thus stronger acids form more stable salts.

## 5.4 Nitrene

Nitrene ( $\Delta H_f = 357(1) \text{ kJ mol}^{-1}$ ,  $S^\circ = 181.253 \text{ J mol}^{-1} \text{ K}^{-1}$ ), also called imidogen radical, nitrogen monohydride, and azene has a triplet ground state ( $X^3\Sigma^-$ ).<sup>39</sup> The reactivity of the first excited singlet state ( $a^1\Delta$ ) is different

from ground-state nitrene because of the difference in its electronic structure. In thermal systems below 1000 K, the ground state is the dominant state. At very high temperatures or in nonthermal systems (photolytic, radiolytic), higher electronic states can be populated. The controlled formation of NH in the electronic ground state is difficult. Thermal decomposition of  $\text{NH}_3$ ,  $\text{NH}_2\text{Cl}$ ,  $\text{N}_2\text{H}_4$ , and  $\text{HNCO}$  yields NH in different electronic states. Photolysis of  $\text{NH}_3$  and  $\text{HN}_3$  produces NH in the first excited state ( $a^1\Delta$ ). Ground-state nitrene is formed in the multiphoton dissociation of  $\text{NH}_3$  at 193 nm. A two-step process also produces ground-state nitrene: first UV photolysis of  $\text{HN}_3$  or  $\text{HNCO}$  that yields NH ( $a^1\Delta$ ) followed by quenching in a Xe or  $\text{N}_2$  matrix to yield NH ( $X^3\Sigma^-$ ).

Ground-state nitrene decomposes to dinitrogen and dihydrogen ( $\Delta H = -331 \text{ kJ mol}^{-1}$ )

Nitrene can be stored for some time below 40 K. At room temperature, nitrene dimerizes very quickly to diimine according to (77).

Nitrene reacts with dioxygen to form nitrous acid and has been observed in a variety of environments including astrophysical studies. It is a key for understanding the fate of nitrogen in combustion systems regardless of the source of nitrogen: dinitrogen, air, or fuel.

## 5.5 Diazene

At low-pressure diazene ( $\Delta H_f = 219.2(8) \text{ kJ mol}^{-1}$ ), also called diimine, is a moderately stable, yellow compound with a lifetime of several minutes at room temperature. It is metastable as a solid below 93 K and very light sensitive.<sup>39</sup>

Evidence for both *cis*-(47) and *trans*-(48) diazene shown in Scheme 17 has been found in IR studies. *Trans*-diazene (48) ( $d(\text{N}-\text{N})$  124.7(1) pm,  $d(\text{N}-\text{H})$  102.9(1) pm,  $\angle(\text{H}-\text{N}-\text{N})$  106.3(2)°) is the dominant structure in the gas phase and has been unambiguously identified. There is evidence that the *cis* isomer (47) is the reactive species in many reactions, for example, in the hydrogenation of organic compounds. A third isomer, the blue-violet, photolabile 1,1-diazene or isodiazene (49) has been detected in matrix-isolation studies at 12 K. It was prepared from aminoisocyanate. Irradiation

Scheme 17 Isomers of diazene

of isodiazene (**49**) at 80 K leads to quantitative formation of dihydrogen and dinitrogen.

The major decomposition path of solid *trans*-diazene (**48**) is the disproportionation to dinitrogen and hydrazine:

The dissociation to dinitrogen and dihydrogen, the dimerization to ammonium azide, and the cleavage to ammonia and dinitrogen are only of minor importance.

Below 400 K, dissolved or gaseous diazene decomposes according to (79). Above 400 K, (80) is the major decomposition path. Gaseous diazene can be stored for some time at room temperature at very low pressures because the decomposition reaction is a bimolecular reaction. The photolytic decomposition of *trans*- $\text{N}_2\text{H}_2$  occurs according to (80) with a radical mechanism via  $\text{NNH}\cdot$ .

Diazene can be prepared by a microwave discharge of hydrazine at low pressures. It is accompanied by an excess of  $\text{NH}_3$  and can be frozen out with ammonia at lower temperatures. Diazene is more stable in ammonia than in the gas phase at room temperature.

The thermal decomposition of tosylhydrazides  $\text{H}_2\text{NNXM}$  ( $\text{X} = p\text{-CH}_3\text{-C}_6\text{H}_4\text{SO}_2$ ,  $\text{M} = \text{alkali metal}$ ) at temperatures between 373 and 393 K, and trapping at 77 K produces diazene, which is almost free of ammonia.<sup>60</sup>

In solution, diimine can be conveniently generated by the protolysis of azodicarbonate:

Diazene is a reducing agent. In the absence of reactive substances, solid or dissolved diazene decomposes in a self-reduction (79). At 77 K, it reacts with dioxygen to form  $\text{H}_2\text{O}_2$  and with  $\text{CCl}_4$  to form  $\text{HCCl}_3$ ,  $\text{H}_2\text{CCl}_2$ , and  $\text{HCl}$ . At 173 K, it reduces sulfuric acid to  $\text{SO}_2$  and  $\text{P}_2\text{O}_5$  to  $\text{P}_4$ . It does not react with  $\text{SiO}_2$ , therefore, glass equipment can be used for the handling of  $\text{N}_2\text{H}_2$ . In organic chemistry, solutions of diazene are used for the hydrogenation of unsaturated compounds,  $\text{N}=\text{N}$ ,  $\text{C}\equiv\text{N}$ ,  $\text{C}=\text{N}$ ,  $\text{S}=\text{O}$ , and  $\text{C}=\text{O}$  bonds.

*Trans*-diazene can be stabilized in complexes (see Scheme 18), where it is normally found as a bridging ligand (**51**). Only one complex is known where it has a

monodentate configuration, as in (**50**) (see *Ammonia & N-donor Ligands*). Diazene complexes are intermediates in biological nitrogen fixation (see *Nitrogenase: Metal Cluster Models* and *Nitrogenase Catalysis & Assembly*).<sup>61</sup>

## 5.6 Triazene

Triazene  $\text{HN}=\text{N}-\text{NH}_2$  is formed in the pulse radiolysis of aqueous solutions of hydrazine.<sup>62</sup> In the radiolysis, diazyl radicals  $\text{N}_2\text{H}_3\cdot$  are formed that dimerize to tetrazene, which decomposes under elimination of ammonia to form triazene.<sup>39</sup>

Triazene has only a limited lifetime, milliseconds in an acidic medium and up to 100 seconds in a basic environment. It decomposes to form ammonia and dinitrogen.

The amphiprotic triazene forms both  $\text{N}_3\text{H}_4^+$  ( $\text{p}K_1 = 4.95$ ) and  $\text{N}_3\text{H}_3^-$  ( $\text{p}K_2 = 11.35$ ).

## 5.7 Tetrazene

*Trans*-2-tetrazene (**52**), which is shown in Scheme 19, forms colorless needles that decompose, sometimes explosively, at 273 K to form dinitrogen and a liquid phase

Scheme 18 Coordination of diazene in complexes

Scheme 19  $\text{N}_4\text{H}_4$  isomers

containing hydrazine and ammonium azide. At temperatures below 243 K, tetrazene can be stored indefinitely.<sup>39</sup> It is soluble in methanol, less soluble in dichloromethane, THF, or trimethylamine. The density of 1.40 g cm<sup>-3</sup> is higher than the density of hydrazine (1.00 g cm<sup>-3</sup>) and is similar to the density of ammonium azide, another N<sub>4</sub>H<sub>4</sub> isomer. In the solid state, *trans*-2-tetrazene (**52**) is found in a gauche conformation. The nitrogen atoms belong to one plane, the lone pairs of all nitrogen atoms are orthogonal to each other (d(N=N) 121(2) pm, d(N-N) 142.9(5) pm, <(H-N-H) 109.8°, <(H1-N-N) 101(4)°, <(H2-N-N) 118(3)°, <(N=N-N) 109(2)°).<sup>63</sup> Hydrogen bonds with NH...N distances of 303–342 pm form a three-dimensional network of tetrazene molecules.

Gaseous 2-tetrazene decomposes only slowly at low pressures to form hydrazinium azide. In solution, 2-tetrazene decomposes above 253 K. It can disproportionate to form dinitrogen and hydrazine or to ammonium azide.

Tetrazene can be obtained from the reaction of tetrazenium salts N<sub>4</sub>H<sub>7</sub><sup>+</sup>X<sup>-</sup> with bases. The tetrazenium salts are formed in small amounts in the decomposition of diazene, which is catalyzed by acids. For the bulk preparation of *trans*-2-tetrazene, the trimethylsilyl derivative of tetrazene is reacted with trifluoroacetic acid at 195 K.<sup>64</sup>

Tetrazene can be purified by sublimation at 253 K. Tetrazenes with organic substituents can be obtained by oxidation of organically substituted hydrazines.

Tetrazene is a weaker base than hydrazine and forms salts N<sub>4</sub>H<sub>5</sub><sup>+</sup>X<sup>-</sup> with strong acids. The salts decompose at temperatures above 253 K to the respective ammonium salt and hydrazoic acid.

Tetrazene is a strong reducing agent that readily forms dinitrogen.

*cis*-2-tetrazene (**53**), the product of protolysis of a cyclic silyl derivative of tetrazene, decomposes instantly at 195 K to form ammonium azide. 1-Tetrazene HN=N-NH-NH<sub>2</sub> is known in form of some unstable organic derivatives that can be synthesized from the reaction of diazonium salts with organic hydrazine derivatives RNHNH<sub>2</sub>. Isotetrazene (H<sub>2</sub>N)<sub>2</sub>N=N (**54**) is only known in the form of the complex

**Table 18** Properties of hydrazoic acid

## 5.8 Hydrazoic Acid and Azide Salts

Hydrazoic acid is a volatile, endothermic liquid of unbearably acid odor. Some of its properties are given in Table 18. Hydrazoic acid and its salts are very toxic. Inhalation of small quantities causes the blood pressure to drop and damages the mucous membranes. Exposure to HN<sub>3</sub> vapors can be recognized by reddening of the eyes. Pure, liquid hydrazoic acid is very sensitive and explodes with slight mechanical stress.<sup>39</sup> It is completely miscible with water and soluble in alcohols and ethers. Tests have shown that aqueous solutions with less than 20% hydrazoic acid do not detonate. Diethylether, which has almost the same boiling point (307.7 K) as HN<sub>3</sub> can be used as a blanketing fluid.

The N<sub>3</sub> unit of HN<sub>3</sub> (C<sub>s</sub>) is angular (d(H-N<sub>α</sub>) 101 pm, d(N<sub>α</sub>-N<sub>β</sub>) 124 pm, d(N<sub>β</sub>-N<sub>γ</sub>) 113 pm, <(H-N-N) 109°, <(N-N-N) 171°). The unsymmetrical structure of covalent azides can be explained by mesomeric resonance, the triple bond structure is the more important Lewis structure.

The bond distances of hydrazoic acid suggest a bond order greater than one for the N<sub>α</sub>-N<sub>β</sub> bond. This fact is explained better by the extended valence bond theory.<sup>65</sup> In (95), two different mesomeric structures are used to explain the bonding properties of HN<sub>3</sub>.<sup>66</sup> The middle structure describes a three-electron bond between N<sub>α</sub>-N<sub>β</sub>, whereas the right (Dewar) structure describes a long bond.

The azide anion, which has a symmetric, linear arrangement of the nitrogen atoms (D<sub>∞h</sub>, d(N-N) 118 pm, <(N-N-N) 180°), is a pseudohalide (see *Pseudohalide*).

HN<sub>3</sub> was first obtained as a product of the oxidation of hydrazine by nitrous acid in aqueous solution:

Today, hydrazoic acid is obtained by the reaction of sodium azide, which is the precursor for all azide compounds, with a stronger acid. Several procedures have been developed for this reaction. Hydrazoic acid has been generated by the reaction of ion-exchange resins, mineral acids, or stearic acid. A convenient way to synthesize anhydrous  $\text{HN}_3$  solutions is the reaction of  $\text{HBF}_4$  with sodium azide in diethylether followed by recondensation of the  $\text{HN}_3$  solution.<sup>67</sup>

### 5.8.1 Production of Azides

For the synthesis of sodium azide, precursors with two nitrogen atoms, hydrazine  $\text{N}_2\text{H}_4$  and  $\text{N}_2\text{O}$ , are used.<sup>5</sup> In the technical process, sodium azide is obtained from dry  $\text{N}_2\text{O}$ , which is passed through a sodium amide melt.

Water reacts with a second molecule of sodium amide to form sodium hydroxide and ammonia.

Since  $\text{N}_2\text{O}$  is formed from sodium amide and sodium nitrate, sodium azide can also be obtained from the reaction of sodium amide and sodium nitrate in liquid ammonia under pressure at 370 K.

### 5.8.2 Chemical Properties of Hydrazoic Acid and Azide Salts

Hydrazoic acid is a weak acid, comparable in strength to acetic acid ( $\text{p}K_{\text{a}} = 4.64$ ).

$\text{HN}_3$  only acts as a base with very strong acids, for example:

The  $C_s$   $\text{N}_3\text{H}_2^+$  ion ( $d(\text{N}_\alpha\text{--N}_\beta)$  1.295(5) pm,  $d(\text{N}_\beta\text{--N}_\gamma)$  1.101(6) pm,  $\angle(\text{H--N--N})$  107(6)°,  $\angle(\text{N--N--N})$  175.3(5)°) has a pyramidal  $\text{NH}_2$  group. The N–N bond distances show that the mesomeric formula with an N–N triple bond is the dominant mesomeric structure.

The weak acid  $\text{HN}_3$  can also react with another azide ion to form the hydrogendiazide anion  $\text{N}_3\text{HN}_3^-$ .<sup>68</sup> The second azide ion is bound to hydrazoic acid via hydrogen bonding with a short  $\text{NH}\cdots\text{N}$  distance of 272(1) pm.

The sometimes explosive decomposition of  $\text{HN}_3$  releases huge amounts of heat ( $\Delta H = -528\text{ kJ mol}^{-1}$ ):

At high temperatures and low pressures,  $\text{HN}_3$  decomposes to form nitrene.

Hydrazoic acid is a strong oxidant ( $E^\circ = 1.96\text{ V}$ ):

It dissolves some metals ( $\text{M} = \text{Zn}, \text{Fe}, \text{Mn}, \text{and Cu}$ ) without evolution of dihydrogen:

In the presence of oxidants, hydrazoic acid is a strong reducing agent ( $E^\circ = -3.09\text{ V}$ ).

Iodine and Ce(IV) salts reduce  $\text{HN}_3$  to dinitrogen. Nitrous acid oxidizes hydrazoic acid to dinitrogen and dinitrogen oxide:

Hydrazoic acid can be reduced electrochemically to hydrazine and ammonia.

The salts of hydrazoic acid, the azides, have similar properties as the respective chlorides, for example,  $\text{AgN}_3$ ,  $\text{Hg}_2(\text{N}_3)_2$ ,  $\text{Pb}(\text{N}_3)_2$ ,  $\text{CuN}_3$ ,  $\text{TlN}_3$  have only low solubility in water. The alkali- and alkaline earth azides have ionic structures. With the exception of  $\text{CsN}_3$  (m.p. 483 K), they do not melt without decomposition. Upon heating, they decompose under evolution of dinitrogen.

The thermal decomposition of sodium azide is used for the preparation of spectroscopically pure dinitrogen.

Heavy metal azides have more covalent structures and detonate upon heating or mechanical stress. Lead diazide  $\text{Pb}(\text{N}_3)_2$  is used as an initiator for explosives. Like chlorine, azide can act as a ligand in complexes. The complex azido anions are often more stable than binary azide complexes (see **Ammonia & N-donor Ligands**).<sup>69</sup> Dinuclear azide complexes are found with two coordination modes of the azide ion, (56) and (57) depicted in Scheme 20.

Anhydrous azide salts or moisture sensitive azides can easily be prepared by the reaction of  $\text{HN}_3$  with the respective metal hydrides, of sodium azide with the respective metal chlorides, or of trimethylsilyl azide with the respective metal fluorides:

### 5.8.2 Covalent Azides

In covalent azides, the pseudohalogen azide  $\text{RN}_3$  has an angular structure as in  $\text{HN}_3$ .<sup>70</sup> Triazidoborazine  $[\text{H}_3\text{N}_3\text{B}_3(\text{N}_3)_3]$  and other boron azides, for example, salts of the tetraazidoborate ion  $\text{B}(\text{N}_3)_4^{6-}$  have been considered as boron nitride precursors (see **Boron–Nitrogen Compounds**). The  $\text{M}(\text{N}_3)_3$  azido complexes of the other group 13 elements (Al, Ga, In, Tl) and their  $\text{M}(\text{N}_3)_4^-$  tetraazido anions are all known. They and their derivatives are also used as precursors for the nitrides.

In group 14, the triazidocarbenium ion  $\text{C}(\text{N}_3)_3^+$  and cyanuric azide  $\text{C}_3\text{N}_3(\text{N}_3)_3$  are molecules with a high-energy content. The triazidocarbenium dinitramide and perchlorate have high positive heats of formation. Nitrophenylazides like 1,3,5-trinitro-2,4,6-triazidobenzene were recently reinvestigated as high-energy materials that produce only gaseous products ( $\text{CO}$  and  $\text{N}_2$ ).<sup>71</sup> While  $\text{Si}(\text{N}_3)_4$  has been reported,<sup>72</sup> no other tetraazides of group 14 are known. The hexaazides  $\text{M}(\text{N}_3)_6^{2-}$  of Si–Pb are remarkably stable when accompanied by large cations, for example,  $\text{AsPh}_4^+$ .<sup>73</sup> Organic derivatives of germanium, tin, and lead diazides and triazides are known, but only lead diazide, which is used as a primary explosive, has been isolated. Silicon and tin azides have been reported as versatile reagents in main group element and organic chemistry.<sup>74</sup>

The phosphorus azides  $\text{P}(\text{N}_3)_3$ ,  $\text{P}(\text{N}_3)_4^+$ ,  $\text{P}(\text{N}_3)_5$ , and  $\text{P}(\text{N}_3)_6^-$  have long been known (see **Phosphorus–Nitrogen Compounds**). More recently, the binary arsenic, antimony, and bismuth  $\text{M}(\text{N}_3)_3$ , the cations  $\text{As}(\text{N}_3)_4^+$  and  $\text{Sb}(\text{N}_3)_4^+$ , and the arsenic and antimony  $\text{M}(\text{N}_3)_4^-$  and  $\text{M}(\text{N}_3)_6^-$  anions have been synthesized.<sup>75</sup> While the cations and binary azides are very sensitive (the bismuth compound has not been isolated), the anions, in combination with sufficiently large cations such as  $\text{As}(\text{Ph})_4^+$ , are less sensitive. Attempts to prepare the As(V) and Sb(V) pentaazides resulted in explosions.

In group 16, the intermediate existence of  $\text{O}(\text{N}_3)_2$  as an intermediate in the reaction of  $\text{OF}_2$  with  $\text{CsN}_3$  has been proposed.<sup>76</sup> Many sulfur azides are known, for details see (see **Sulfur: Inorganic Chemistry**). Binary selenium and tellurium azides are not known, but several organic derivatives of the azides have been synthesized.<sup>77,78</sup> For a description of the halogen azides, see Section 8.6.

### 5.9 Ammonium Azide

Ammonium azide is a colorless, crystalline substance. Some of its properties are given in Table 19. No phase transitions are found between 90 and 348 K. Sublimation of ammonium azide begins at 406 K, recondensation of the vapors at 418 K. Ammonium azide vapors decompose, similar to other ammonium salts, to ammonia and  $\text{HN}_3$  at 418 K ( $\Delta H = +67.7 \text{ kJ mol}^{-1}$ ). In the solid state, all ammonium ions are tetrahedrally connected to azide ions via hydrogen bonds with an  $\text{NH}\cdots\text{N}$  distance of 297.5(4) and 296.7(3) pm.<sup>39</sup>

Ammonium azide is synthesized either by reacting solutions of  $\text{HN}_3$  with ammonia:

or by dry heating of sodium azide with ammonium nitrate, whereby the produced ammonium azide sublimes to colder parts of the reaction vessel. Great care has to be taken in this reaction because of the thermal sensitivity of ammonium nitrate.

The reaction of sodium azide with ammonium sulfate or ammonium chloride in dimethylformamide at 358–393 K under reduced pressure also leads to ammonium azide:

The detonation of ammonium azide produces a huge amount of gas ( $\Delta H = -158 \text{ kJ mol}^{-1}$ ).

An activation energy of  $110 \text{ kJ mol}^{-1}$  was found for the explosion of ammonium azide. Irradiation at wavelengths  $< 300 \text{ nm}$  results in decomposition to ammonia and dinitrogen:

### 5.10 Hydrazinium Azide

Hydrazinium azide ( $\Delta H_f = +246.6 \text{ kJ mol}^{-1}$ ,  $\Delta H_{\text{fusion}} = +15.8 \text{ kJ mol}^{-1}$ ,  $\rho = 1.40 \text{ g cm}^{-3}$ ) is the salt of the weak acid  $\text{HN}_3$  with the weak base hydrazine. It is a colorless, hygroscopic solid (m.p. 348 K, b.p. 443 K) that easily sublimes.<sup>38</sup> A phase change between 268 and 273 K has been detected. The hydrazinium ions in the crystal structure have a staggered configuration, and every hydrogen atom of the hydrazinium ions is involved in hydrogen bonding with azide ions. The  $\text{NH}\cdots\text{N}$  distances of the hydrogen bonds between hydrazinium ions and azide ions are between 282.4 and 291.8 pm. There is also a weak hydrogen bond between the hydrazinium ions with an  $\text{NH}\cdots\text{N}$  distance of 338 pm. Table 20 shows a comparison of the bonding parameters between ammonium azide, hydrazinium azide, and its hydrazine adduct.

Hydrazinium azide is prepared by the reaction of hydrazine with hydrazoic acid. To avoid the handling of the hazardous  $\text{HN}_3$ , which is generally synthesized by the reaction of sodium azide with an acid, several procedures have been developed for this reaction. Hydrazoic acid has been generated by the reaction of ion-exchange resins, mineral acids, or stearic acid. It was then either passed through a solution of hydrazine in an inert gas stream or a solution of hydrazoic acid was added to a solution of hydrazine. Especially pure hydrazinium azide can be obtained by the reaction of anhydrous solutions of  $\text{HN}_3$  in diethyl ether with a suspension of anhydrous hydrazine in

diethyl ether (97). Hydrazinium azide was also observed in the decomposition of 5-aminotetrazole and *trans*-2-tetrazene.

The first step in the decomposition of liquid hydrazinium azide is the dissociation to hydrazine and  $\text{HN}_3$ .

$\text{HN}_3$  reacts with hydrazinium azide to form  $\text{NH}_3$  and  $\text{N}_2$ .

The overall equation for the decomposition of hydrazinium azide between 400 and 570 K was found to be:

Detonation of hydrazinium azide in an argon atmosphere under 3 MPa pressure produces ammonia, dinitrogen, and dihydrogen.

Both hydrazinium azide and its hydrazinate have been tested in explosive mixtures and as gas generators, but so far they are not in use.

### 5.11 Hydrazinium Azide Hydrazinate

The hydrazine adduct of hydrazinium azide, hydrazinium azide hydrazinate ( $\Delta H_f = +294(3) \text{ kJ mol}^{-1}$ ,  $\rho = 1.320 \text{ g cm}^{-3}$ ) is a colorless solid (m.p. 338 K).<sup>79</sup> Every hydrogen atom of the hydrazine molecules is involved in hydrogen bonding. The  $\text{NH}\cdots\text{N}$  distances are between 294.5(2) and 313.5(2) pm. The hydrazinium ion and the hydrazine molecule are connected by a long hydrogen bond with an  $\text{NH}\cdots\text{N}$  distance of 313.5(2) pm, forming a formal  $(\text{N}_2\text{H}_4)_2\text{H}^+$  cation.

Hydrazinium azide hydrazinate can be synthesized by heating a mixture of hydrazinium azide and an equimolar amount of hydrazine to 333 K for several days.

The detonation of hydrazinium azide hydrazinate under pressure produces ammonia, dinitrogen, and dihydrogen.

**Table 20** Bonding parameters of  $\text{N}_2\text{H}_5\text{N}_3$  and  $\text{N}_2\text{H}_5\text{N}_3 \cdot \text{N}_2\text{H}_4$

## 6 NITROGEN OXIDES

The nitrogen oxides, shown in Table 21, except  $\text{N}_2\text{O}_4$  (l) and  $\text{N}_2\text{O}_5$  (s), are endothermic compounds and all nitrogen

**Table 21** Binary nitrogen oxides

compounds are endergonic compounds ( $\Delta G_f > 0$ ) and should therefore decompose to the elements at room temperature.<sup>5</sup> Owing to kinetic barriers, decomposition begins only at higher temperatures. The monomeric nitrogen oxides NO, NO<sub>2</sub>, and NO<sub>3</sub> are radicals.<sup>65</sup> Some properties of the nitrogen oxides are summarized in Table 22.

The nitrogen oxides NO<sub>x</sub> are important in globally relevant tropospheric and stratospheric processes. Their life and fate is related to the ozone molecule due to manifold interactions both between the neutral and charged species. The anthropogenic emission of nitrogen oxides is now in the same order of magnitude as the natural emission of nitrogen oxides. Bacteria produce dinitrogen oxide from NH<sub>4</sub><sup>+</sup> during nitrification, and from NO<sub>3</sub><sup>−</sup> in the denitrification process. N<sub>2</sub>O (t<sub>1/2</sub> about 100 years) is inert under tropospheric conditions, but reacts in the stratosphere under the influence of oxygen radicals and ultraviolet radiation.

Nitric oxide radicals (t<sub>1/2</sub> about 2–3 years) destroy ozone in a catalytic process. In the stratosphere, they also stem from emissions from planes and rockets, and reactions of N<sub>2</sub>O with

solar protons

The overall reaction of this process is:

Ozone is formed by the photolytic decomposition of NO<sub>2</sub> yielding oxygen radicals and by the reaction sequence NO<sub>2</sub> → HNO<sub>3</sub> → NO<sub>3</sub> → O<sub>3</sub>. In particular, the reaction of NO<sub>2</sub> with hydroxyl radicals to form HNO<sub>3</sub> increases ozone concentration because two radicals, NO<sub>2</sub>· and ·OH, which catalyze ozone decomposition, are removed. Other radicals are also important for ozone destruction in the stratosphere, especially chlorine oxides (see *Chlorine, Bromine, Iodine, & Astatine: Inorganic Chemistry*). The mechanism of ozone destruction is complicated as there many compounds involved. Chlorine nitrate and dinitrogen pentoxide can act as reservoir species for ClO·, NO<sub>2</sub>·, and NO<sub>3</sub>· radicals.

Nitric oxide in the troposphere (t<sub>1/2</sub> about 1 day) stems from bacteria, lightning and for the main part from emissions of combustion engines.

The oxidation of nitric oxide in small concentrations in the troposphere by dioxygen is very slow. As shown in Scheme 21, nitric oxide is oxidized to nitrogen dioxide (t<sub>1/2</sub> several days) either by HOO· radicals or by ozone. Reaction of nitrogen dioxide with hydroxide radicals forms nitric acid (t<sub>1/2</sub> several days). Rain washes nitric acid out, thus acidic rain is formed.

**Table 22** Properties of nitrogen oxides

|                                                                       | N <sub>2</sub> O | NO      | N <sub>2</sub> O <sub>3</sub> | NO <sub>2</sub> /N <sub>2</sub> O <sub>4</sub> | N <sub>2</sub> O <sub>5</sub> |

<sup>a</sup>Dissociation to NO and NO<sub>2</sub>.

Scheme 21 Reactions of tropospheric nitrogen oxides

Carbon monoxide is oxidized in the troposphere ((133) and (134)). With a high concentration of nitric oxide in the troposphere, reactions (135) and (136) take place. This sequence is a formation of ozone catalyzed by nitric oxide. If the nitric oxide concentration is too low, the perhydroxyl radicals decompose ozone to form hydroxyl radicals (136). Ozone and peroxyacetyl nitrates PAN are the major toxins of smog. Peroxyacetyl nitrates are formed from aldehydes in a reaction catalyzed by nitric oxide.

### 6.1 Nitrosyl Azide

Nitrosyl azide is formed in the reaction of an excess of activated sodium azide with nitrosyl chloride at 218 K.<sup>80</sup>

Nitrosyl azide can be sublimed under partial decomposition at low temperatures to form a pale yellow solid. Upon warming, it decomposes to form dinitrogen oxide and dinitrogen.

Calculations indicate the formation of a cyclic  $\text{N}_4\text{O}$  isomer as an intermediate during this decomposition.<sup>81</sup> A  $\text{N}_3\text{O}^+$  cation has been detected mass spectroscopically in the detonation products of nitromethane.<sup>82</sup>

### 6.2 Nitryl Azide

The reaction of nitronium hexafluoroantimonate with sodium azide at 223 K in carbon dioxide yields nitryl azide.<sup>83</sup>

On warming up to room temperature, nitryl azide decomposes to dinitrogen oxide.

### 6.3 Dinitrogen Monoxide

Dinitrogen monoxide ( $\Delta H_f^\circ = +82.10\text{ kJ mol}^{-1}$ ), also called nitrous oxide, is a colorless, diamagnetic gas with a weak, pleasant odor, and a sweet taste. The melting point of  $\text{N}_2\text{O}$  is 182.3 K; its boiling point is 184.7 K. It is insoluble in water.<sup>4</sup>

$\text{N}_2\text{O}$  has a linear geometry with an N–O distance of 118.6 pm and an N–N distance of 112.6 pm. The N–N bond can be regarded to be between a double and triple bond, the N–O bond is between a single and a double bond. The extended valence bond structures in (142) describe the observed N–N and N–O bond lengths in  $\text{N}_2\text{O}$  better. The right structure gives is the best representation of the actual bonding situation.<sup>84</sup>

A cyclic  $\text{N}_2\text{O}$  isomer has not been detected yet,<sup>81</sup> but theoretical calculations indicate its formation in the decomposition of nitrosyl azide and in the reaction of  $\text{OF}_2$  with cesium azide. Dinitrogen monoxide is only metastable at lower temperatures, at temperatures above 870 K it decomposes to the elements ( $\Delta H = +82.10\text{ kJ mol}^{-1}$ ):

Dinitrogen monoxide is relatively unreactive at room temperature; it does not react with alkaline metals, ozone, chlorine, bromine, or iodine. Easily flammable materials (phosphorus (see *Phosphorus–Nitrogen Compounds*), sulfur (see *Sulfur–Nitrogen Compounds*), coal (see *Carbon: Inorganic Chemistry*)) burn in a dinitrogen oxide atmosphere as in an oxygen atmosphere, though it is more difficult to start the combustion in dinitrogen monoxide. A mixture of  $\text{N}_2\text{O}$  and dihydrogen (see *Hydrogen: Inorganic Chemistry*) explodes with slightly less force than a dioxygen/dihydrogen mixture because of the formation of dinitrogen ( $\Delta H = +1012.1\text{ kJ mol}^{-1}$ ).

Under UV irradiation,  $\text{N}_2\text{O}$  reacts with difluorine to form nitrosodifluoramine (see Section 9.4). Dinitrogen monoxide is synthesized by the thermal decomposition of ammonium

nitrate or mixtures of sodium nitrate and ammonium sulfate at about 500 K:

At first, this process used solid ammonium nitrate and great care had to be taken to avoid an explosive decomposition of ammonium nitrate (54), which starts at higher temperatures. Now aqueous solutions of ammonium nitrate are used. By-products in this reaction are  $\text{N}_2$  and NO.

Laboratory syntheses of nitrous oxide include the decomposition of hyponitrous acid (236) or nitramide (314), the reaction of nitrous acid with hydroxylamine (146) or hydrazoic acid, (147) and the reaction of amidosulfonic acid with concentrated nitric acid (148):

Dinitrogen monoxide can act as a Lewis base in complexes (monodentate in  $[\text{Ru}(\text{NH}_3)_5(\text{N}_2\text{O})]^{2+}$ ). It can also act as a Lewis acid with strong Lewis bases, for example, in the reaction with amides to form azides.

Dinitrogen monoxide is used in medicine as an anesthetic because, when inhaled, it can bring about a spasmodic inclination to laugh and a condition resembling drunkenness, which explains its historic name, laughing gas. It is also used as a propellant in the munitions industry and a foaming agent for whipped cream in the food industry.

#### 6.4 Nitrogen Monoxide and Dinitrogen Dioxide

Nitrogen monoxide ( $\Delta H_f = +90.25 \text{ kJ mol}^{-1}$ ), also called nitric oxide, is a colorless, paramagnetic, and toxic gas. Impurities of  $\text{N}_2\text{O}_3$  can cause a blue color of the liquid (b.p. 121.38 K, m.p. 115.5 K). It is only slightly soluble in water. Nitrogen monoxide is the simplest known, thermally stable molecule (d(N–O) 114 pm) with an odd number of electrons (see *Electronic Structure of Main-group Compounds*) and is a chemical messenger in biological systems. NO helps to regulate a diverse array of physiological processes, such as neurotransmission and blood pressure, and prevents blood clots (see *Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry*).

The structure with the three electron bond between nitrogen and oxygen is the best description of the bonding situation in nitric oxide.

Nitrogen monoxide partly dimerizes upon condensation. At room temperature the dimerization equilibrium is on the side of NO ( $\Delta H = -10.5 \text{ kJ mol}^{-1}$ ).

In the liquid and especially in the solid state (diamagnetic), the equilibrium is on the side of the diamagnetic dimer.

As the MO scheme (Scheme 22) shows, the unpaired electron in nitric oxide is in an antibonding MO, thus the bond order is 2.5 and the ionization energy is rather low compared to dinitrogen, dioxygen or carbon monoxide ( $\text{IE}(\text{NO}) = 9.25 \text{ eV}$ ,  $\text{IE}(\text{N}_2) = 15.6 \text{ eV}$ ,  $\text{IE}(\text{CO}) = 14.0 \text{ eV}$ ,  $\text{IE}(\text{O}_2) = 12.1 \text{ eV}$ ). The two antibonding  $\pi^*$  orbitals of NO form a bond in the dimer (see Figure 5). The antibonding  $\pi^*$  orbital is closer to nitrogen, thus explaining the shorter nitrogen–nitrogen bonds.<sup>65</sup>

While both the *cis* (58) and the *trans* (59) isomer in Scheme 23 have been observed, the *cis* isomer (58) (d(N–O) 112(2) pm, d(N–N) 218(3) pm, d(O–O) 2.62(3) pm)<sup>85</sup> is more stable. A red asymmetric dimer (60) has been detected when NO is condensed in the presence of Lewis acids like  $\text{BX}_3$  ( $\text{X} = \text{Hal}$ ),  $\text{SiF}_4$ ,  $\text{SnCl}_4$ ,  $\text{TiCl}_4$ ,  $\text{SO}_2$ , or  $\text{HCl}$ .

NO can form a molecule with an even number of electrons either by oxidation to the  $\text{NO}^+$  cation (d(N–N) 106 pm), which is isoelectronic with CO and  $\text{N}_2$  and has a nitrogen–oxygen triple bond or by reduction to form the nitroxyl anion  $\text{NO}^-$ , which is isoelectronic to dioxygen  $\text{O}_2$ .

The highly endothermic nitric oxide can be synthesized from the elements dinitrogen and dioxygen in an electric arc ( $\Delta H = 180.6 \text{ kJ mol}^{-1}$ ). This also takes place in the natural nitrogen fixation by lightning.

Nitric oxide is only formed at very high temperatures (equilibrium concentration about  $10^{-7}$  vol% NO (500 K), 0.04% (1000 K), 0.1% (1500 K), 0.5% (1800 K), and 1% at 2100 K). Around 2300 K, the NO concentration reaches a maximum; at higher temperatures the NO decomposition is faster than the NO formation. The nitric oxide formation has a radical mechanism, starting with the homolytic dissociation of dioxygen to form oxygen radicals.

The chain reaction consists of oxygen radicals reacting with dinitrogen molecules to form NO and nitrogen radicals, which

Figure 5 Bonding in the NO dimer

Scheme 22 MO scheme of nitric oxide

react with dioxygen to form NO and oxygen radicals.

The process stops on the combination of nitrogen and oxygen radicals.

In former technical processes for the synthesis of nitric oxide, the reaction gases had to be rapidly cooled below 725 K. Slow cooling would give the equilibrium concentration of nitric oxide at the appropriate temperature. At temperatures lower than 725 K, nitric oxide is metastable and does not decompose to dinitrogen and dioxygen. Careful control of the

reaction conditions can yield nitric oxide concentrations of about 3%. Nitric oxide is a side product in all combustion processes that employ air and has to be disposed off to avoid pollution of air and the detrimental effects of nitric oxide in the atmosphere (see Section 6). Owing to the preventive energy consumption, the process was only ever practiced in countries with cheap waterpower like Norway and Switzerland and has been completely replaced by the catalytic combustion of  $\text{NH}_3$  in the Ostwald process (see Section 7.8.1).<sup>5</sup>

Nitric oxide can be obtained conveniently in the laboratory by the reduction of nitric acid with copper, mercury, or iron(II) salts.

A very pure nitric oxide is available from the reduction of acidic nitrite solutions with iodide or iron(II) salts.

Nitric oxide decomposes at temperatures higher than 725 K in the reverse of its formation (152) to dinitrogen and dioxygen.

Scheme 23  $\text{N}_2\text{O}_2$  isomers

Compressed, liquid, and nitric oxide included in zeolites decompose slowly in an exothermic process:

At higher pressures and temperatures above 323 K it decomposes to:

In the presence of air or dioxygen, nitric oxide is oxidized to the brown nitrogen dioxide ( $\Delta H = 114.2 \text{ kJ mol}^{-1}$ ).

The equilibrium of this exothermic reaction is shifted to the left side at higher temperatures. At temperatures higher than 925 K, almost all nitrogen dioxide has decomposed to nitric oxide and dioxygen. The mechanism of the oxidation of NO with dioxygen is assumed to have an ONOONO intermediate that isomerizes to the nitrite isomer of  $\text{N}_2\text{O}_4$ . It has not been proven whether a ONOO intermediate is formed in the first step.<sup>86</sup>

Nitric oxide forms nitrosyl halides in the reaction with chlorine and bromine (see Section 9.1); in the reaction with fluorine, both nitrosyl fluoride and trifluoramine oxide are formed (see Section 9.3).

Strong oxidizing agents such as  $\text{KMnO}_4$ ,  $\text{HOCl}$ , or  $\text{K}_2\text{CrO}_4$  oxidize nitric oxide to nitrate (158) in acidic solution ( $E^\circ = 0.96 \text{ V}$ ). Strong reducing agents reduce nitric oxide to dinitrogen or ammonia. Coal, phosphorus, and magnesium burn vigorously in nitric oxide atmosphere.

Nitric oxide, in contrast to nitrogen dioxide, does not react with water. It reacts with concentrated solutions of strong bases or with alkali metal oxides at 373 K to form nitrite and hyponitrite, which decomposes under these conditions forming  $\text{N}_2\text{O}$  and  $\text{Na}_2\text{O}$ .

In coordination compounds, NO is more electronegative than CO and a weaker  $\sigma$ -donor than CO, but a stronger  $\pi$ -acceptor.

In mononuclear complexes, NO is found either in a linear geometry (61) (which can still have small deviations) or in an angular geometry (62). In the linear geometry, the NO ligand coordinates as  $\text{NO}^+$  and is considered a three-electron donor. In the angular geometry, the NO ligand coordinates as  $\text{NO}^-$  and is considered a one-electron donor. Scheme 24 summarizes different modes of no coordination.

In multinuclear complexes, NO can act as a bridging ligand, bridging two (63) or three metal atoms (64). NO has one electron more than CO, therefore the atomic number of the metal centers of NO complexes are lower than in similar CO complexes (see *Carbonyl Complexes of the Transition Metals*), for example,  $\text{Ni}(\text{CO})_4$ ,  $\text{Co}(\text{CO})_3\text{NO}$ ,  $\text{Fe}(\text{CO})_2(\text{NO})_2$ ,  $\text{Mn}(\text{CO})(\text{NO})_3$ , and  $\text{Cr}(\text{NO})_4$ . For more information on nitrosyl complexes, see Reference 87.

## 6.5 Dinitrogen Trioxide

Pure dinitrogen trioxide ( $\Delta H_f = +86.6(1) \text{ kJ mol}^{-1}$ ) is a pale blue solid ( $\rho = 1.781 \text{ g cm}^{-3}$ ) that melts at 172.6 K to form an intensively blue liquid.  $\text{N}_2\text{O}_3$  partially decomposes in the range of 233 K to 270 K. At 233 K, the vapor phase contains NO and  $\text{N}_2\text{O}_3$ , while the liquid phase contains  $\text{N}_2\text{O}_3$  and the equilibrium mixture of  $\text{NO}_2$  and  $\text{N}_2\text{O}_4$ . The liquid assumes a green hue due to the mixed colors of blue  $\text{N}_2\text{O}_3$  and brown  $\text{NO}_2$ . At higher temperatures,  $\text{NO}_2$  is also found in the vapor phase and at ambient temperatures  $\text{N}_2\text{O}_3$  vapors only contain about 10% undissociated  $\text{N}_2\text{O}_3$ . Solutions of  $\text{N}_2\text{O}_3$  in organic solvents also have a blue color.

Dinitrogen trioxide has a planar  $C_s$  structure.<sup>88</sup> The nitrogen–nitrogen bond in  $\text{N}_2\text{O}_3$  of 186 pm in the gas phase and 189 pm in the solid state is significantly longer than the bond distances found for N–N single bonds, for example, in hydrazine. It corresponds to a Pauling bond order of 0.2.  $\text{N}_2\text{O}_3$  can be described as nitrosyl nitrite  $\text{NO}^+\text{NO}_2^-$ . The N1–O1 distance is with 112 pm between the N–O distance of NO of 115 pm and  $\text{NO}^+$  with 106.5 pm. The N–O bond length of 121 pm and the O–N–O bond angle of  $129^\circ$  of the  $\text{NO}_2$  group are in good agreement with  $\text{N}_2\text{O}_4$  ( $d(\text{N–O}) =$

**Scheme 24** Coordination of NO in nitrosyl complexes

118 pm,  $\angle(\text{O}-\text{N}-\text{O}) = 134^\circ$ ) and  $\text{NO}_2^-$  ( $d(\text{N}-\text{O}) = 124$  pm,  $\angle(\text{O}-\text{N}-\text{O}) = 115^\circ$ ). A comparison between solid-state and gas-phase bonding parameters is shown in Table 23.

A second isomer (**65**) of  $\text{N}_2\text{O}_3$  shown in Figure 6 with the connectivity ONONO was detected in matrix-isolation experiments.

It is assumed to be an intermediate in the nitration of organic compounds in solution. After irradiation at 380 nm, it reverts to the  $\text{ONNO}_2$  structure.

Nitric oxide and nitrogen dioxide form  $\text{N}_2\text{O}_3$  upon cooling ( $\Delta H = +40.6(1) \text{ kJ mol}^{-1}$ ).

Therefore, dinitrogen trioxide can be synthesized by adding an equimolar amount of NO to liquid  $\text{NO}_2$  or by adding a stoichiometric amount of dioxygen to  $\text{NO}_2$ .<sup>5</sup>

The equilibrium (166) is easily shifted to either side, therefore an equimolar mixture of NO and  $\text{NO}_2$  has the same reactivity as  $\text{N}_2\text{O}_3$ , the anhydride of nitrous acid:

In basic solutions, NO and  $\text{NO}_2$  are absorbed to form nitrites.  $\text{N}_2\text{O}_3$ , which is responsible for the nitrite formation, is formed according to the equilibrium (166).

In strong acids, the nitrosyl cation  $\text{NO}^+$  is formed from  $\text{N}_2\text{O}_3$ .

**Table 23** Bonding parameters of  $\text{N}_2\text{O}_3$

|                                                      | X-ray     | Microwave |

**Figure 6** ONONO Isomer of  $\text{N}_2\text{O}_3$

$\text{N}_2\text{O}_3$  is used as a powerful nitrosating agent in organic chemistry. It is also used for preparing high-purity alkali nitrites.

## 6.6 Nitrogen Dioxide and Dinitrogen Tetroxide

Nitrogen dioxide ( $\Delta H_f = +34.2(5) \text{ kJ mol}^{-1}$ ) is a brown, paramagnetic, corrosive, and highly toxic gas with a characteristic pungent odor. Below the melting point of 262 K, it forms a brown liquid that loses its intensity upon cooling, until at 258 K a colorless solid is formed. The color change is due to the equilibrium of the  $\text{NO}_2$  radical (brown) with its dimer  $\text{N}_2\text{O}_4$  (colorless).

The dissociation enthalpy in the gas phase is  $57.3(1) \text{ kJ mol}^{-1}$ . Below the freezing point, only  $\text{N}_2\text{O}_4$  exists. The pale yellow liquid at the freezing point contains 0.01%  $\text{NO}_2$ . At the boiling point, the liquid changes to an intense red-brown color with 0.1%  $\text{NO}_2$ , the vapor phase contains 20%  $\text{NO}_2$ . At 373 K, the vapor phase contains 90%  $\text{NO}_2$  and at 413 K  $\text{N}_2\text{O}_4$  is completely dissociated. At temperatures higher than 423 K,  $\text{NO}_2$  starts to decompose ( $\Delta H = +114.2 \text{ kJ mol}^{-1}$ ), and decomposition is complete at 873 K.

Paramagnetic nitrogen dioxide is, like nitric oxide, a molecule with an odd number of electrons (see *Electronic Structure of Main-group Compounds*) and has an angular structure ( $C_{2v}$ ,  $d(\text{N}-\text{O}) = 119.5(3)$  pm (GED), 119.455(3) (MW);  $\angle(\text{O}-\text{N}-\text{O}) = 133.7(2)^\circ$  (GED), 133.852(2) (MW)).<sup>89</sup> The repulsive interaction of lone pairs of electrons can be observed in the bond angles of  $\text{NO}_2^+$ ,  $\text{NO}_2$ , and  $\text{NO}_2^-$ .  $\text{NO}_2^+$ , which has no lone electrons and has a linear structure;  $\text{NO}_2$ , which has one lone electron has a  $\text{O}-\text{N}-\text{O}$  angle of  $133.7^\circ$  and  $\text{NO}_2^-$ , which has a lone pair, has a  $\text{O}-\text{N}-\text{O}$  angle of  $115.4^\circ$ .

A better bonding description is given by the extended valence bond structures:

Diamagnetic dinitrogen tetroxide ( $\Delta H_f(\text{g}) = +11.1(1) \text{ kJ mol}^{-1}$ ) has a planar ( $D_{2h}$ ) geometry (**66**). The activation energy for internal rotation is estimated to be  $40 \text{ kJ mol}^{-1}$ , the twisted isomer has been detected under nonequilibrium conditions. Table 24 shows a comparison of the bonding parameters of  $\text{N}_2\text{O}_4$  in the solid state and in the gas phase.

**Scheme 25** Isomers of dinitrogen tetroxide**Table 24** Bonding parameters of  $N_2O_4$

$N_2O_4$  forms two phases in the solid state, a cubic and a monoclinic phase.<sup>90</sup> The monoclinic phase is only formed during crystallization from liquid  $N_2O_4$  with small impurities and can transform to the standard cubic phase, whereas the cubic phase does not transform to the monoclinic phase. The *syn* (67) and *anti* (68) nitrite isomers of  $N_2O_4$  shown in Scheme 25 were identified in low-temperature matrices of  $N_2$  and  $O_2$ .<sup>91</sup> The less stable of these forms converts to the ionic form of  $N_2O_4$  and  $NO^+NO_3^-$  upon warming. Self ionization of  $N_2O_4$  has been implicated in the solution chemistry of  $N_2O_4$ , and occurs as a reversible phase transition at 2.5 GPa for solid  $N_2O_4$ , although the molecular form  $O_2NNO_2$  is metastable to very high pressures when compressed as a single crystal.<sup>92</sup> Self oxidation of NO at 80 K also results in a red solid that is described as  $NO^+NO_3^-$  on the basis of its IR spectrum. If  $N_2O$  is compressed to 10–30 GPa at temperatures of 1000–2000 K,  $NO^+NO_3^-$  is formed in the following reaction:

Once formed,  $NO^+NO_3^-$  is stable below 180 K. At room temperature, it is stable with a pressure greater than 1.0 GPa. At higher temperatures/lower pressures,  $NO^+NO_3^-$  transforms to molecular  $N_2O_4$  (66).<sup>93</sup> Weak electron donor solvents can form complexes of the type  $D \cdot N_2O_4$  and strong electron donor solvents stabilize the ionic form of  $N_2O_4$ :  $NO^+NO_3^-$ .  $N_2O_4$  dissolves in  $IF_5$  with a yellow color, forming an adduct of the type  $NO^+NO_3^- \cdot IF_5$ .<sup>94</sup> An  $ONOOONO$  isomer of  $N_2O_4$  is assumed to be an intermediate in the oxidation of NO with dioxygen, and isomerizes to the nitrite isomers of  $N_2O_4$ , (67) and (68).

In nitrogen dioxide, one electron is in a  $\pi^*$  antibonding orbital like in nitric oxide. A bonding interaction between two dinitrogen oxide molecules with partly filled  $\pi^*$  antibonding orbitals leads to a six center three-electron interaction (see Figure 7), explaining the planar structure and the long N–N bond of 176 pm in dinitrogen tetroxide.

$NO_2/N_2O_4$  is produced industrially by the Ostwald process (see Section 7.8.1),<sup>5</sup> by the catalytic oxidation of ammonia to NO, and oxidation of NO with dioxygen.<sup>5</sup> Other commercial processes for producing  $NO_2/N_2O_4$  are the oxidation of nitrosyl chloride yielding chlorine as by-product and the treatment of sodium nitrite with nitric acid followed by oxidation of the liberated nitrogen monoxide to nitrogen dioxide. High-purity  $NO_2/N_2O_4$  is obtained in the production of sodium nitrate from sodium chloride and nitric acid. In the laboratory,  $NO_2$  is accessible by the reduction of concentrated nitric acid with copper:

Even more convenient is dry heating of heavy metal nitrates, especially lead(II)nitrate to 620–850 K:

Dinitrogen oxide is a strong oxidizing agent ( $E^\circ = 1.03\text{ V}$ ) (see Scheme 26 and Scheme 27) with a similar oxidation potential to  $Br_2$ .

Potassium, sulfur (see **Sulfur–Nitrogen Compounds**), phosphorus (see **Phosphorus–Nitrogen Compounds**), coal (see **Carbon: Inorganic Chemistry**), and dihydrogen (see **Hydrogen: Inorganic Chemistry**) burn in an  $NO_2$  atmosphere more intensively than in an NO or  $N_2O$  atmosphere.  $NO_2$  forms explosive mixtures with hydrogen; mixtures with ammonia

**Figure 7** Bonding in dinitrogen tetroxide

pH = 0

Scheme 26 Standard potentials for nitrogen compounds at pH = 0

pH = 14

Scheme 27 Standard potentials for nitrogen compounds at pH = 14

explode even at low temperature. It can also react explosively with organic compounds in a radical chain reaction with the first step:

$\text{NO}_2$  can also act as a reducing agent with powerful oxidizing agents like  $\text{O}_3$  or  $\text{H}_2\text{O}_2$ .

The reaction of  $\text{NO}_2$  with fluorine or chlorine yields nitryl halides (see Section 9.2).

$\text{N}_2\text{O}_4$  is between the anhydride of nitrous acid,  $\text{N}_2\text{O}_3$ , and the anhydride of nitric acid,  $\text{N}_2\text{O}_5$ , and is the anhydride of both nitrous and nitric acid:

In the reaction with bases, nitrates and nitrites are formed.

Liquid  $\text{N}_2\text{O}_4$  can be used as a nonaqueous solvent.<sup>95</sup> The low electric conductivity  $1.3 \times 10^{-13} \Omega^{-1} \text{cm}^{-1}$  indicates that autodissociation to nitrosonium and nitrate ions does not take place in liquid  $\text{N}_2\text{O}_4$ .

Weak electron donor solvents can form complexes of the type  $\text{D}\cdot\text{N}_2\text{O}_4$  and strong electron-donor solvents stabilize the ionic form of  $\text{N}_2\text{O}_4$ :  $\text{NO}^+\text{NO}_3^-$ .  $\text{N}_2\text{O}_4$  dissolves in  $\text{IF}_5$  with a yellow color, forming an adduct of the type  $\text{NO}^+\text{NO}_3^-\cdot\text{IF}_5$ . It consists of double chains of alternating  $\text{NO}^+$  and  $\text{NO}_3^-$  ions

separated by layers of  $\text{IF}_5$  molecules. Distillation of the  $\text{IF}_5$  adduct returns covalent  $\text{N}_2\text{O}_4$ .

The nitrosonium cations in liquid  $\text{N}_2\text{O}_4$  react as oxidizing agents, for example, for the oxidation of metals.

Nitrosonium ions also react as Lewis bases with Lewis acids like halides or oxides.

The nitrate ions remaining from the dissociation of  $\text{N}_2\text{O}_4$  react as Lewis bases with metal cations.

Many metal salts dissolve in  $\text{N}_2\text{O}_4$ . Sn, Cu, and Zn dissolve in  $\text{N}_2\text{O}_4$  to form the metal dinitrates.

These reactions are a convenient preparation of anhydrous nitrates, especially if the metal bromides or iodides are dissolved in  $\text{N}_2\text{O}_4$ .

Often nitrato complexes with nitrosonium cations  $(\text{NO}^+)_m$   $\text{M}(\text{NO}_3)_n^{(n-m)-}$  are formed.

Another example is the intriguing  $[(\text{NO}^+)_3\text{NO}^-]^\dagger$   $[\text{Fe}(\text{NO}_3)_4]_2^-$ . Here the cation consists of a nitrate anion surrounded by three  $\text{NO}^+$  cations.

$\text{N}_2\text{O}_4$  is a donor for nitronium and nitrite ions:

An example is the reaction with  $\text{BF}_3$ , where  $\text{NO}_2^+$   $[\text{NO}_2^- \cdot \text{BF}_3]^-$  is formed.

The strong oxidizing agent dinitrogen tetroxide is used for many applications. It is employed as a catalyst in oxidation reactions and as an inhibitor in the distillation of acrylates. It is also used in the manufacture of explosives and as bleach. In rocket propellants, it is used in a hypergolic mixture with hydrazine derivatives.<sup>51</sup> The command module of the Apollo mission used a 1:1 mixture of hydrazine and  $N,N'$ -dimethylhydrazine with  $\text{N}_2\text{O}_4$  as the oxidant.

## 6.7 Dinitrogen Pentoxide

Dinitrogen pentoxide ( $\Delta H_f = -43.1 \text{ kJ mol}^{-1}$ ) is a colorless, light, and heat sensitive solid that is deliquescent in air and sublimates at 305.5 K. It melts under pressure at 314 K and decomposes at room temperature. The decomposition is sometimes explosive, especially at higher temperatures.

In the gas phase and in unpolar solvents like  $\text{CCl}_4$ ,  $\text{N}_2\text{O}_5$  consists of two  $\text{NO}_2$  groups linked by a bridging oxygen atom with a nonlinear N–O–N group.<sup>96</sup> The equilibrium structure has a torsion angle of  $30^\circ$  ( $C_2$ ); the rotation along the N–O single bonds has an activation barrier of about 4–8  $\text{kJ mol}^{-1}$ .

In the solid state, ( $\rho(78 \text{ K}) = 2.175 \text{ g cm}^{-3}$ ;  $\rho(288 \text{ K}) = 2.05 \text{ g cm}^{-3}$ ) and when dissolved in strong acids like nitric acid,  $\text{N}_2\text{O}_5$  has an ionic nitronium nitrate  $\text{NO}_2^+\text{NO}_3^-$  structure. When gaseous  $\text{N}_2\text{O}_5$  is rapidly cooled below 80 K, the molecular structure is conserved. Upon reheating to 200 K, the ionic structure is formed. Table 25 shows a comparison of the bonding parameters of  $\text{N}_2\text{O}_5$  in the solid state and in the gas phase.

In the gas phase,  $\text{N}_2\text{O}_5$  dissociates ( $\Delta H = 95.6(1.5) \text{ kJ mol}^{-1}$ ) to nitrogen dioxide and nitrogen trioxide, which can decompose further according to (202) and (203). This

**Table 25** Bonding parameters of  $\text{N}_2\text{O}_5$

|                                                   | X-ray | GED                  |

makes  $\text{N}_2\text{O}_5$  an important nighttime reservoir in atmospheric chemistry for the reactive  $\text{NO}_2^\bullet$  and  $\text{NO}_3^\bullet$  species.<sup>97</sup>

Dinitrogen pentoxide is the anhydride of nitric acid, and was industrially prepared by the careful dehydration of nitric acid with phosphorus pentoxide.

A newer synthesis produces 10–20% solutions of  $\text{N}_2\text{O}_5$  in nitric acid by electrolysis of nitric acid in the presence of  $\text{N}_2\text{O}_4$ .

Pure and almost acid free  $\text{N}_2\text{O}_5$  is obtained from the oxidation of dinitrogen tetroxide with ozone.

$\text{N}_2\text{O}_5$  is a strong oxidant and reacts violently with many types of reductants, including metals, nonmetals, and numerous organic compounds.

The dissociation to  $\text{NO}_2^+\text{NO}_3^-$  in strong acids is a convenient pathway to nitronium salts like  $(\text{NO}_2^+)_2\text{S}_2\text{O}_7^{2-}$  from the reaction with  $\text{SO}_3$  or  $\text{NO}_2^+\text{FSO}_3^-$ .

Dinitrogen pentoxide forms an adduct  $\text{N}_2\text{O}_5 \cdot \text{BF}_3$  ( $\text{NO}_2^+(\text{BF}_3 \cdot \text{ONO}_2^-)$ ) with boron trifluoride, which is a good nitrating reagent. The reaction of  $\text{N}_2\text{O}_5$  with halogens  $\text{X}_2$  ( $\text{X} = \text{F}, \text{Cl}$ ) forms nitryl halides  $\text{XNO}_2$ .

$\text{N}_2\text{O}_5$  is slowly replacing nitrating acid ( $\text{HNO}_3 + 2\text{H}_2\text{SO}_4$ ) in some applications, because nitration with pure nitrogen pentoxide is acid free and can take place in an anhydrous solvent. For nitration, a dilute solution of  $\text{N}_2\text{O}_5$  in chlorinated organic solvents like  $\text{CH}_2\text{Cl}_2$  is used.

### 6.8 Nitrogen Trioxide

$\text{NO}_2$  and excess dioxygen form nitrogen trioxide ( $\Delta H_f = 74(1) \text{ kJ mol}^{-1}$ ) in a glow discharge.

The nitrogen trioxide radical has a  $D_{3h}$  structure ( $d(\text{N}-\text{O}) = 120.4 \text{ pm}$ ). The spin density of nitrogen is zero for symmetrical reasons and the unpaired electron is located at the oxygen atoms.

The reaction of  $\text{NO}_2$  and  $\text{N}_2\text{O}_5$  with ozone as well as the decomposition of  $\text{N}_2\text{O}_5$  yields  $\text{NO}_3\cdot$ .  $\text{NO}_3\cdot$  decomposes according to two dissociation channels:

The mechanism for the formation of nitric oxide (202) is still unclear.

The formation of an intermediate  $\text{ONOO}$  (**69**) species in Figure 8 has been claimed in a spectroscopic study but was later questioned due to multireference calculations.<sup>98</sup>  $\text{NO}_3$  reacts with  $\text{NO}_2$  to form dinitrogen pentoxide.<sup>97</sup>

$\text{N}_2\text{O}_5$  acts as a reservoir species in atmospheric chemistry making  $\text{NO}_3$ , formed by the dissociation of  $\text{N}_2\text{O}_5$ , the major nighttime oxidant in the stratosphere.

Figure 8  $\text{ONOO}$  isomer of  $\text{NO}_3$

A mass spectrometric investigation of  $\text{NO}_2/\text{O}_3/\text{O}_2$  mixtures with chemical ionization has identified the  $\text{NO}_5^+$  cation from the reaction of  $\text{NO}_2^+$  with ozone.<sup>99</sup> The decomposition products  $\text{NO}_4^+$  and  $\text{NO}_3^+$  indicate an  $\text{O}_n\text{NO}_2$  connectivity of  $\text{NO}_5^+$  and its decomposition products.

Mixtures of  $\text{NO}/\text{O}_3/\text{O}_2$  also produce  $\text{NO}_4^+$  ions under the conditions described above, but their decomposition products indicate an  $\text{O}_3\text{NO}$  connectivity. Three isomeric  $\text{NO}_3^+$  cations have been detected in the mixtures described above under different conditions: one has  $\text{O}_2\text{NO}$  connectivity and two share  $\text{O}-\text{NO}_2$  connectivity, but with different structures. One  $\text{NO}_3^+$  cation has a trigonal structure like the radical  $\text{NO}_3\cdot$ , the other corresponds to a weakly bound species that undergoes a near threshold decomposition and is assumed to have  $\text{ONOO}$  connectivity. Neutralisation-reionization mass spectrometry of this  $\text{NO}_3^+$  isomer shows weak evidence for a neutral  $\text{ONOO}$  isomer (**69**) with a lifetime exceeding  $1 \mu\text{s}$ .

## 7 OXOACIDS OF NITROGEN

The strength of the nitrogen oxoacids given in Table 26 increases with higher oxidation numbers of nitrogen. While hydroxylamine is only a very weak acid, nitrous acid is an acid of medium strength and nitric acid is a very strong acid. The anions of orthonitric acid  $\text{HNO}_4$  and oxohyponitric acid  $\text{H}_2\text{N}_2\text{O}_3$  are known, but the free acids have not yet been observed.  $\text{HNO}$  and  $\text{HNOO}$  are not stable at standard conditions and are metastable at lower temperatures. Salts with the formula  $\text{M}_3\text{NO}_3$ , formally salts of orthonitrous acid  $\text{H}_3\text{NO}_3$ , are obtained from the reaction of equimolar amounts of alkali metal nitrites with alkali metal oxides  $\text{M}_2\text{O}$ .<sup>100</sup>

Yellow  $\text{Na}_3\text{NO}_3$ , red  $\text{K}_3\text{NO}_3$ , and red-brown  $\text{Rb}_3\text{NO}_3$  do not contain the orthonitrite anion  $\text{NO}_3^{3-}$ , but are mixed crystals of the salts  $\text{MNO}_2$  and  $\text{M}_2\text{O}$  with an anti-perovskite  $(\text{NO}_2)\text{OM}_3$

Table 26 Oxoacids of nitrogen in different oxidation states

| Oxidation state | Formula                          | Name                           | Salt                         |
|-----------------|----------------------------------|--------------------------------|------------------------------|
| −1              | $\text{H}_2\text{NOH}$           | hydroxylamine                  | hydroxylamide                |
| 0               | $\text{HNOO}$                    | imine peroxide                 | —                            |
| +1              | $\text{HNO}$                     | nitrosyl hydride (nitroxyl)    | nitroxyl anion               |
|                 | $\text{HONNOH}$                  | hyponitrous acid               | hyponitrite                  |
| +2              | $\text{H}_2\text{N}_2\text{O}_3$ | oxohyponitric acid, only salts | hyponitrate, trioxodinitrate |
| +3              | $\text{HNO}_2$                   | nitrous acid                   | nitrite                      |
|                 | $\text{HONOO}$                   | peroxonitrous acid             | peroxonitrite                |
| +5              | $\text{HNO}_3$                   | nitric acid                    | nitrate                      |
|                 | $\text{H}_3\text{NO}_4$          | orthonitric acid, only salts   | orthonitrate                 |
|                 | $\text{HNO}_4$                   | peroxonitric acid              | peroxonitrate                |
| —               | $\text{H}_2\text{NNO}$           | nitrosamine                    | —                            |
| —               | $\text{H}_2\text{NNO}_2$         | nitramide                      | —                            |
| —               | $\text{HN}(\text{NO}_2)_2$       | dinitramic acid                | dinitramide                  |

structure.<sup>101</sup> The trialkoxyamines (RO)<sub>3</sub>N, organic derivatives of orthonitric acid, are also unstable species.

Reduction of a solution of sodium nitrite in ammonia with sodium produces a deep yellow solid with the formula Na<sub>2</sub>NO<sub>2</sub>, sodium nitroxylate.

The compound has only a small paramagnetic susceptibility. The unexpected low paramagnetic susceptibility suggests that the compound dimerizes to Na<sub>4</sub>N<sub>2</sub>O<sub>4</sub>, and is dissociated to about 20% to Na<sub>2</sub>NO<sub>2</sub> at room temperature. The structure of this salt is unknown.<sup>102</sup>

The oxidation potentials of nitrogen compounds in different oxidation states are shown in Scheme 26 and Scheme 27. The oxidants are stronger in acidic solution and the reductants are stronger in basic solution. The strongest oxidants are hyponitrous acid H<sub>2</sub>N<sub>2</sub>O<sub>2</sub> and HNO<sub>3</sub>, the strongest reductants NH<sub>2</sub>OH and N<sub>2</sub>O<sub>2</sub><sup>2-</sup>. It follows that dinitrogen N<sub>2</sub> cannot disproportionate to compounds with any oxidation state. Nitrogen fixation is not possible this way. On the other hand, depending on the pH of the medium, hydroxylamine can disproportionate to form ammonia and dinitrogen, and hyponitrous acid can disproportionate to form nitrous acid and dinitrogen. Nitrous acid can disproportionate to form nitric acid and dinitrogen.

## 7.1 Hydroxylamine

Hydroxylamine crystallizes as colorless needles ( $\Delta H_f^\circ = -114 \text{ kJ mol}^{-1}$ ), which melt at 305 K. The boiling point of liquid hydroxylamine is 329.5 K at 22 HPa and the density is 1.204 g cm<sup>-3</sup> at 306 K. The N–O bond distance is 146 pm in the gas phase and 147 pm in the solid state. Other gas-phase bonding parameters include: d(O–H) = 96 pm, d(N–H) = 101 pm, <(H–O–N) = 103°, <(H–N–O) = 105°, <(H–N–H) = 107°. In the solid state (Figure 9), hydrogen bonds connect hydroxylamine molecules with a *trans* conformation (70). The NH⋯O distance is 274 pm.

Hydroxylamine can disproportionate to form ammonia and dinitrogen or dinitrogen oxide:

Pure hydroxylamine or its aqueous solutions can be stored for several weeks in the absence of oxygen at low temperatures.

**Figure 9** Structure of hydroxylamine molecules in the solid state

The decomposition rate increases with increasing pH. In the presence of oxygen, for example, in air, pure hydroxylamine or its aqueous solution decompose rapidly, especially at slightly elevated temperatures. At temperatures above 373 K, hydroxylamine decomposes explosively. Autoxidation takes place in basic solutions in the presence of transition metals and dioxygen. Hydroxylamine is oxidized to nitrite via nitrosyl and peroxonitrite ions.

### 7.1.1 Production of Hydroxylamine

Hydroxylamine is prepared by reducing nitrogen oxides in higher oxidation states, for example, nitric oxide, nitrous acid, or nitric acid.<sup>5</sup>

For reduction of nitric oxide, a mixture of nitric oxide and dihydrogen is passed through a suspension of a platinum (BASF process) or palladium in sulfuric acid. Ammonium sulfate and dinitrogen oxide are by-products.

Nitrous acid can be reduced to hydroxylamine with sulfurous acid:

In the Raschig process, ammonium nitrite is converted to ammonium hydroxylamine disulfonate with sulfur dioxide in sulfuric acid at 273 K:

The sulfonate is then hydrolyzed at 373 K to form hydroxylammonium sulfate and ammonium sulfate.

A phosphoric acid/ammonium nitrate buffer solution with a suspended noble metal catalyst can be reduced with hydrogen to hydroxylammonium dihydrogenphosphate:

The hydroxylammonium solution is then directly used for oxime formation and the consumed nitrate ions are replaced by addition of nitric acid.

Nitric acid can also be reduced between lead electrodes in the presence of hydrochloric or sulfuric acid:

The acidic cleavage of nitroalkanes has only found limited use due to its cost and the limited availability of the raw materials.

### 7.1.2 Anhydrous Hydroxylamine

All hydroxylamine syntheses yield hydroxylammonium salts. Free hydroxylamine can be prepared by adding a strong base to the hydroxylammonium salts. Sodium methanolate  $\text{NaOCH}_3$  can be used for this purpose:

After the reaction, the solid sodium salt is filtered off and methanol is distilled off under reduced pressure. Hydroxylamine can also be prepared by the ammonolysis of hydroxylammonium salts in liquid ammonia. The ammonium salt precipitates and is filtered off. Hydroxylamine is obtained after evaporating the excess ammonia.

### 7.1.3 Chemical Properties of Hydroxylamine

As a hydroxyderivative of ammonia, hydroxylamine is a weak base ( $\text{p}K_{\text{b}} = 8.2$ ) and forms hydroxylammonium salts with acids:

In contrast to free  $\text{NH}_2\text{OH}$ , the hydroxylammonium salts are relatively stable. Dry hydroxylammonium salts disproportionate upon heating to form the ammonium salts and dinitrogen.<sup>4</sup>

The hydroxylammonium salts ( $\text{p}K_{\text{a}} = 5.8$ ) are more acidic in aqueous solution than the ammonium salts ( $\text{p}K_{\text{a}} = 9.25$ ) because  $\text{NH}_2\text{OH}$  is less basic than  $\text{NH}_3$ .  $\text{NH}_2\text{OH}$  is a weak acid ( $\text{p}K_{\text{a}} = 13.7$ ), only slightly more acidic than water. The hydroxylamides  $\text{NH}_2\text{O}^-$ , of which the sodium, calcium, and zinc salts are known, are very unstable and explosive.

Like ammonia, hydroxylamine can form complexes in basic solution (see *Ammonia & N-donor Ligands*), coordinating via the nitrogen atom as in (71) in Scheme 28. Complexes of the deprotonated hydroxylamides show  $\text{N}_2\text{O}$

**Scheme 28** Coordination of hydroxylamine and the hydroxylamide ion in complexes

coordination as in (72). Both coordination modes are found in  $[\text{UO}_2(\text{ONH}_2)(\text{HONH}_2)]$ .

Hydroxylamine ( $E^\circ = 1.87 \text{ V}$ ) is a strong reducing agent (see Scheme 26 and Scheme 27).

$\text{N}_2$  and  $\text{N}_2\text{O}$  are the products of the oxidation of hydroxylamine. With an excess of oxidizing agent,  $\text{NO}$ ,  $\text{NO}_2^-$ ,  $\text{NO}_2$ , as well as  $\text{NO}_3^-$  are formed. Hydroxylamine reacts as an oxidant with reducing agents ( $E^\circ = 1.35 \text{ V}$ ).

One-electron oxidants like  $\text{Ce}^{4+}$ ,  $\text{Mn}^{3+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Co}^{3+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Ag}^+$ , or  $\text{Ag}^{2+}$  generate the intermediate radical  $\cdot\text{NHOH}$  that can react with  $\text{Ce}^{4+}$ ,  $\text{Mn}^{3+}$ , or  $\text{Cu}^{2+}$  to form  $\text{HNO}$ :

which in turn forms  $\text{N}_2\text{O}$

or decomposes directly to form dinitrogen (with  $\text{Co}^{3+}$ ,  $\text{Fe}(\text{CN})_6^{4-}$ ).

Two-electron oxidants such as  $\text{CrO}_4^{2-}$ ,  $\text{MnO}_4^-$ , or  $\text{ClO}^-$  produce  $\text{N}_2\text{O}$  via  $\text{HNO}$ .

$\text{Sn}(\text{II})$ ,  $\text{V}(\text{II})$ , or  $\text{Cr}(\text{II})$  salts can reduce hydroxylamine to ammonia, here the amino radical  $\text{NH}_2\cdot$  is an intermediate.

Reaction of hydroxylamine with ketones or aldehydes yields oximes, aldoximes  $\text{RHC}=\text{NOH}$ , or ketoximes  $\text{R}_2\text{C}=\text{NOH}$ . Almost all the hydroxylamine production (95%) is used for the production of either cyclohexanone oxime or caprolactam, both of which are intermediates for polyamide synthetics. The remainder of the hydroxylamine production is used as an anticreaming agent in paints and coatings, as an auxiliary in refining fats for soap production, as a regulator or inhibitor for various polymerizations, as a stabilizer for developers, and as an additive for color emulsions. Oximes are also used as pharmaceuticals or in crop protection.

## 7.2 Nitrosyl Hydride (Nitroxyl)

The reaction of atomic hydrogen with  $\text{NO}$  at  $77 \text{ K}$  yields a pale yellow substance with the composition  $\text{HNO}$  that

condenses on the walls of the reaction vessel ( $\Delta H_f = +107 \text{ kJ mol}^{-1}$ ). At 178 K, it decomposes to form hyponitrous acid  $\text{H}_2\text{N}_2\text{O}_2$  (80%) and dinitrogen oxide (20%). HNO is also a reactive intermediate of the oxidation of hydroxylamine  $\text{NH}_2\text{OH}$  and the reduction of nitrous acid  $\text{HNO}_2$ . It dimerizes to hyponitrous acid  $\text{H}_2\text{N}_2\text{O}_2$ . HNO is also formed during the decomposition of Angeli's salt  $\text{Na}_2\text{N}_2\text{O}_3$ :

The weak acid HNO ( $\text{p}K_a = 11.4$ ) has a singlet ground state ( $X^1A'$ ).<sup>103</sup> The nitroxyl anion  $\text{NO}^-$  has a triplet ground state ( $X^3\Sigma^-$ ), therefore the dissociation of HNO to  $\text{NO}^-$  and  $\text{H}^+$  is spin forbidden and inherently slow. In physiological systems, HNO is the dominant form, but  $\text{NO}^-$ , once formed, has sufficient lifetime to react with other species. HNO is like NO a transient intermediate in physiological systems.

The nitroxyl anion dimerizes to form hyponitrite:

The isomer HON was detected in matrix isolation and is in a photoequilibrium with HNO.<sup>104</sup>

Reaction of the nitroxyl anion  $\text{NO}^-$  with dioxygen  $\text{O}_2$  forms peroxonitrite, which isomerizes in acidic solution to nitrate.

The presence of HNO as an intermediate in this reaction can be verified with the violet complex  $[\text{Ni}(\text{CN})_3\text{NO}]^{2-}$ :

In HNO complexes, the HNO molecule ( $d(\text{N}=\text{O})$  120 pm,  $\angle(\text{H}-\text{N}-\text{O})$  99°) is bonded via nitrogen and has a bent conformation.

### 7.3 Imine Peroxide

The reaction of ground-state nitrene  $\text{NH}(X^3\Sigma^-)$  with molecular oxygen in argon or xenon matrices at temperatures of 20 K yields imine peroxide.<sup>105</sup>

It is also formed in the photodissociation of matrix-isolated methyl nitrate that yields either  $\text{HNO}_2$  (hydrogen nitryl) or imine peroxide  $\text{HNOO}$ .<sup>106</sup>

Theoretical calculations suggest that HNOO has a singlet electronic ground state with considerable diradical character, similar to ozone. HNOO is, therefore, a member of the group of 1,3-dipole molecules whose electronic structure has been described as a resonance of the zwitterionic versus the radical structure.

A *cis* and a *trans* form are possible for HNOO. However, only one form, probably the *trans* form, was detected in the matrix-isolation experiments. Imine peroxide isomerizes to nitrous acid upon irradiation with UV or IR light.

### 7.4 Hyponitrous Acid

The hydroxygroups of hyponitrous acid are found in a *trans* (73) and a *cis* (74) conformation (Scheme 29). The nitridonitrate isomer (75) is only known in form of its tautomer, nitramide.

While *trans*-hyponitrous acid has been known for a long time, only salts of *cis*-hyponitrous acid are stable. The isolated  $\text{N}_2\text{O}_2^{2-}$  dianion, which was insulated from stabilizing cations in solid argon, has been observed with matrix-isolation techniques and is one of the smallest known dianions that is stable toward electron loss.<sup>107</sup>

#### 7.4.1 *trans*-Hyponitrous Acid

*trans*-Hyponitrous acid forms colorless rods, which are very sensitive when dry and decompose violently.<sup>108</sup> A comparison of the bonding parameters of several  $\text{N}_2\text{O}_2^{2-}$  compounds is given in Table 27.

**Scheme 29** Isomers of hyponitrous acid

**Table 27** Structural data of  $\text{N}_2\text{O}_2^{2-}$  compounds

|              | <i>trans</i> - $\text{H}_2\text{N}_2\text{O}_2^a$ | <i>trans</i> - $\text{HN}_2\text{O}_2^{-a}$ | <i>trans</i> - $\text{N}_2\text{O}_2^{2b}$ | <i>cis</i> - $\text{N}_2\text{O}_2^{2-c}$ |
|--------------|---------------------------------------------------|---------------------------------------------|--------------------------------------------|-------------------------------------------|

| d(N-O) [pm]  | 136.3(3)                                          | NOH 140.2(3)<br>NO 137.1(3)                 | 1.389(1)                                   | 140(1)                                    |
| <(N-N-O) [°] | 109.0(3)                                          | NNOH 110.1(2)<br>NNO 108.2(2)               | 107.6(1)                                   | 120.8(4)                                  |

<sup>a</sup>[HEt<sub>2</sub>NCH<sub>2</sub>CH<sub>2</sub>NEt<sub>2</sub>H][HN<sub>2</sub>O<sub>2</sub>]<sub>2</sub>·H<sub>2</sub>N<sub>2</sub>O<sub>2</sub>; <sup>b</sup>[2,2'-bipyridinium][N<sub>2</sub>O<sub>2</sub>]; <sup>c</sup>*cis*-Na<sub>2</sub>N<sub>2</sub>O<sub>2</sub>.

*trans*-H<sub>2</sub>N<sub>2</sub>O<sub>2</sub> is obtained by reducing nitrous acid with sodium amalgam at 273 K:

After the reaction is finished, the insoluble silver hyponitrite Ag<sub>2</sub>N<sub>2</sub>O<sub>2</sub> is precipitated with AgNO<sub>3</sub>. H<sub>2</sub>N<sub>2</sub>O<sub>2</sub> is accessible by treating the silver salt with a solution of HCl gas in diethyl ether, or by oxidation of hydroxylamine with copper, silver, or mercury oxide.

Aqueous solutions of *trans*-hyponitrous acid are acidic (pK<sub>1</sub> = 7.21, pK<sub>2</sub> = 11.54) and decompose slowly, faster at higher temperatures, via HO-N=N-O<sup>-</sup> to form water and dinitrogen oxide (*t*<sub>1/2</sub> (298 K) = 16 days at pH = 1–3, at higher pH values *trans*-H<sub>2</sub>N<sub>2</sub>O<sub>2</sub> is unstable).

This reaction is not reversible, and dissolving of N<sub>2</sub>O in water does not give hyponitrous acid. As a dibasic acid, *trans*-hyponitrous acid forms two types of salts: acidic hyponitrites M<sup>+</sup> HN<sub>2</sub>O<sub>2</sub><sup>-</sup> that decompose readily and are more stable, and neutral hyponitrites M<sub>2</sub><sup>+</sup>N<sub>2</sub>O<sub>2</sub><sup>2-</sup>. Both types of salts react basic, are reductants, and are remarkably stable against reduction.

Reaction of iodine with *trans*-hyponitrous acid yields nitrous acid and nitric acid:

Nitrous acid reduces *trans*-hyponitrous acid to dinitrogen:

Liquid N<sub>2</sub>O<sub>4</sub> oxidizes *trans*-hyponitrous acid stepwise: N<sub>2</sub>O<sub>2</sub><sup>2-</sup> → N<sub>2</sub>O<sub>3</sub><sup>2-</sup> → N<sub>2</sub>O<sub>4</sub><sup>2-</sup> → N<sub>2</sub>O<sub>5</sub><sup>2-</sup> → N<sub>2</sub>O<sub>6</sub><sup>2-</sup>.

#### 7.4.2 *cis*-Hyponitrites

Disodium *cis*-hyponitrite can be obtained by passing NO through a solution of sodium in liquid ammonia:

Reaction of disodium oxide and dinitrogen oxide at 633 K also yields disodium *cis*-hyponitrite.<sup>109</sup>

Disodium *cis*-hyponitrite is very sensitive to moisture and CO<sub>2</sub>.

Thermal decomposition of *cis*-Na<sub>2</sub>N<sub>2</sub>O<sub>2</sub> leads to sodium orthonitrite.

*cis*-Hyponitrite is found in transition metal complexes as a chelating ligand in the yellow (PH<sub>3</sub>)<sub>2</sub>Pt(N<sub>2</sub>O<sub>2</sub>) with a PtO<sub>2</sub>N<sub>2</sub> five-membered ring and as a bridging ligand that is coordinated via one nitrogen atom and one oxygen atom in red [(H<sub>3</sub>N)<sub>5</sub>Co(N<sub>2</sub>O<sub>2</sub>)Co(NH<sub>3</sub>)<sub>5</sub>]<sup>4+</sup>. The reaction of diazenium diolates with metal chlorides can be used for the synthesis of chelating *cis*-hyponitrite complexes.<sup>110</sup>

#### 7.5 Oxohyponitrous Acid

Oxohyponitrous acid is not known. The trioxodinitrate anion (**76**) in Figure 10 is planar (d(N1–O1) 131.0(4) pm, d(N2–O2/3) 132.2(4) pm, d(N–N) 126.4(5) pm, <(O2–N2–O3) 119.1(5)°, <(O1–N–N) 118.4(3)°).

It is relatively stable in very basic solutions and forms insoluble precipitates with alkaline earth, lead, and cadmium dications. Dioxygen oxidizes the trioxodinitrate anion.

The monoanion HN<sub>2</sub>O<sub>3</sub><sup>-</sup> is found in mildly basic to mildly acidic solution and is very sensitive toward oxidation by

**Figure 10** Structure of the trioxodinitrate dianion

dioxygen. It is unstable and decomposes via HNO to form  $\text{N}_2\text{O}$  and nitrite:<sup>111</sup>

The proton of  $\text{HN}_2\text{O}_3^-$  is bound to a nitrogen atom according to  $\text{O}_2\text{N}-\text{NH}-\text{O}^-$ . Addition of nitrite to an aqueous solution of  $\text{HN}_2\text{O}_3^-$  shifts the dissociation equilibrium (246) to the left side and stabilizes the protonated anion.

Oxohyponitrous acid, an acid of medium strength ( $\text{p}K_1 = 2.4$ ,  $\text{p}K_2 = 9.4$ ), is unstable like the  $\text{HN}_2\text{O}_3^-$  anion. The same is true for very acidic solutions of  $\text{N}_2\text{O}_3^{2-}$ . The decomposition of the free acid is catalyzed by nitrite ions, traces of which are initially formed during decomposition of  $\text{HN}_2\text{O}_3^-$ .

This reaction is not reversible, therefore, NO is not the anhydride of oxohyponitrous acid.

The disodium salt of oxohyponitrous acid, Angeli's salt, is formed by the nitration of hydroxylamine  $\text{HONH}_2$  with alkyl nitrates  $\text{RNO}_3$  in methanol with sodium methanolate at 273 K.

## 7.6 Nitrous Acid

Planar nitrous acid forms two isomers (Scheme 30). The *trans* form (77) ( $\Delta H_f = -80.18 \text{ kJ mol}^{-1}$ ,  $d(\text{N}=\text{O}) 117.7 \text{ pm}$ ,

**Scheme 30** Isomers of nitrous acid

$d(\text{N}-\text{O}) 143.3 \text{ pm}$ ,  $d(\text{O}-\text{H}) 95.4 \text{ pm}$ ),  $\angle(\text{O}-\text{N}-\text{O}) 110.7^\circ$ ,  $d(\text{N}-\text{O}-\text{H}) 102.1^\circ$  is more stable than the *cis* isomer (78) ( $\Delta H_f = -78.04 \text{ kJ mol}^{-1}$ ) in the gas phase and is the only one observed in the gas phase.<sup>4</sup> Another tautomeric form, the  $C_{2v}$  structure (79), was detected as an intermediate in the photodissociation of nitric acid in noble gas matrices. Organic derivatives of both forms play important roles in industrial chemistry. Organic derivatives  $\text{R}-\text{NO}_2$  of the  $C_{2v}$  structure (79) are called nitro compounds; derivatives  $\text{ONOR}$  of the  $C_s$  structures (77) and (78) are called nitrite esters. Nitro complexes (80) that contain the  $-\text{NO}_2$  ligand (e.g.  $\text{K}_3[\text{Co}(\text{NO}_2)_6]$ ) are more stable than nitrito complexes (81) with the  $-\text{ONO}$  ligand. Because nitrito complexes are usually less dense, nitro and nitrito complexes can be transformed into each other. The red nitro complex  $[\text{Ni}(\text{en})_2(\text{NO}_2)_2]$  is converted to the violet nitrito complex  $[\text{Ni}(\text{en})_2(\text{ONO})_2]$  on raising the temperature from room temperature to 400 K. Application of 2 MPa pressure at 400 K reverses the change. An in plane rotation of the nitro group is responsible for these changes. The nitrite ion also shows chelating (82) ( $[\text{Cu}(\text{ONO})(2,2'\text{-bipy})_2]\text{NO}_3$ ), unsymmetrical bridging (83) ( $[\text{Ni}(\text{en})_2\text{NO}_2]^+$ ), and  $\eta^1$  bridging (84) coordination ( $\{\text{Cu}(2,2'\text{-dipyridylamine})\text{NO}_2\}_2(\mu^1\text{NO}_2)_2$ ) (see Scheme 31).

The nitrite ion is isoelectronic to ozone and NOF, and has an angular structure ( $d(\text{N}-\text{O}) = 123.6 \text{ pm}$ ,  $\angle(\text{O}-\text{N}-\text{O}) 115.4^\circ$ ).

Nitrous acid is only stable in dilute, cold aqueous solution and in the form of its salts, the nitrites. Upon heating or increasing the concentration, the following equilibria are in effect:

**Scheme 31** Coordination modes of nitrite ligands

The equilibrium constant  $K$  of (251) at room temperature is around 0.2, therefore a  $0.1 \text{ mol L}^{-1}$  solution of nitrous acid contains  $0.002 \text{ mol L}^{-1}$   $\text{N}_2\text{O}_3$ . In total, nitrous acid disproportionates to nitric acid and NO.

Aqueous solutions of nitrous acid are synthesized by the reaction of nitrite salts with strong acids. The reactions of silver nitrite with HCl and barium nitrite with sulfuric acid both produce insoluble precipitates that can easily be separated from the nitrous acid solution.

Anhydrous nitrous acid can be prepared in the gas phase; liquid  $\text{HNO}_2$  has not been isolated.

The disproportion reaction (255) shows that nitrous acid can react both as an oxidizing or reducing agent. In combination with strong oxidizing agents like  $\text{MnO}_4^-$ ,  $\text{BrO}_3^-$ ,  $\text{O}_2$ ,  $\text{H}_2\text{O}_2$ , or  $\text{PbO}_2$ , nitrous acid acts as a reducing agent ( $E^\circ = 0.949 \text{ V}$ ).

Nitrous acid acts as an oxidizing agent toward iodides, iron(II) salts, and oxalates. ( $E^\circ = 0.996 \text{ V}$ ).

Other compounds reduce nitrous acid to  $\text{H}_2\text{N}_2\text{O}_2$  (sodium amalgam,  $\text{H}_2\text{NOH}$ ),  $\text{N}_2\text{O}$  (Sn(II) salts),  $\text{N}_2$  ( $\text{NH}_3$ ),  $\text{HN}_3$  ( $\text{N}_2\text{H}_4$ ),  $\text{H}_2\text{NOH}$  ( $\text{H}_2\text{SO}_3$ ), or  $\text{NH}_3$  ( $\text{H}_2\text{S}$ ).

Nitrous acid is a moderately weak acid ( $\text{p}K_a = -3.35$  at  $291 \text{ K}$ ). Aqueous solutions of nitrite salts contain nitrous acid and are therefore not very stable. Nitrous acid is an extremely weak base:

Only very strong, concentrated acids produce the nitrosyl cation in small concentrations (e.g.  $9 \text{ mol L}^{-1}$  sulfuric acid).  $\text{NO}^+$  reacts with nitrous acid to form  $\text{N}_2\text{O}_3$ .

Therefore, pouring sulfuric acid over nitrites results in the formation of both NO and  $\text{NO}_2$ . Nitrates do not form brown gases on reaction with sulfuric acid, a reaction that is used for the analytic distinction between nitrates and nitrites.

With the exception of silver nitrite, which is only slightly soluble, nitrite salts readily dissolve in water. The alkali metal nitrites and ammonium nitrite are hygroscopic. While sodium nitrite melts without decomposition, most other nitrites decompose before reaching the melting point ( $\text{Ba}(\text{NO}_2)_2 > 593 \text{ K}$ ,  $\text{AgNO}_2 > 413 \text{ K}$ ,  $\text{Hg}(\text{NO}_2)_2 > 348 \text{ K}$ ). Ammonium nitrite decomposes above  $333 \text{ K}$ , sometimes explosively, to dinitrogen and water:

Ammonium nitrite is only stable as a dry solid; it can be used to prepare very pure nitrite salts on reaction with hydroxides.

The reaction of alkali metal nitrites with alkali metal oxides  $\text{M}_2\text{O}$  yields salts  $\text{M}_3\text{NO}_3$  that do not contain the orthonitrite anion  $\text{NO}_3^{3-}$  but are mixed crystals of the salts  $\text{MNO}_2$  and  $\text{M}_2\text{O}$  with anti-perovskite structure  $(\text{NO}_2)\text{ONa}_3$ .<sup>100,101</sup> Some properties of important nitrite salts are given in Table 28.

Sodium nitrite, the most important nitrite salt, is produced by the reaction of nitrogen oxides with sodium carbonate or sodium hydroxide solution.<sup>5</sup> Formation of nitrates can be inhibited by using an excess of NO and working with a pH higher than 8.

Sodium nitrite is still the most reliable agent for preventing botulism, a dangerous bacterial contaminant of meats and in curing salts is used in the food industry. High nitrite concentrations can, however, lead to the formation of carcinogenic nitrosamines. Nitrous acid and its salts are used in nitrosation reactions. The nitrosation of aromatic amines leads to diazonium compounds (for dyes). Primary aliphatic amines form the corresponding alcohol and dinitrogen upon nitrosation with nitrous acid. Secondary aliphatic amines form *N*-nitrosamines and  $\text{R}_2\text{NNO}$  and tertiary aliphatic alcohols form trialkylammonium nitrites  $\text{R}_3\text{NH}^+ \text{NO}_2^-$ , which react further to an alcohol and the dialkyl nitrosamines  $\text{R}_2\text{NNO}$  upon warming.

## 7.7 Peroxohyponitrous Acid

The peroxonitrite ion has a partial double bond between nitrogen and the first peroxide oxygen. As shown in

**Table 28** Properties of important nitrite salts

|                                      | $\text{NH}_4\text{NO}_2$ | $\text{NaNO}_2$ | $\text{KNO}_2$ |
|--------------------------------------|--------------------------|-----------------|----------------|
| m.p. [K]                             | –                        | 557             | 714 (decomp.)  |
| $\Delta H_f$ [kJ mol <sup>-1</sup> ] | –260(5)                  | –358(2)         | –375(5)        |
| $\rho$ [g cm <sup>-3</sup> ]         | 1.69                     | 2.168           | 1.915          |

Scheme 32, the molecule exists in a *cis* (**85**) and a *trans* form (**86**).<sup>112</sup>

The *cis* form (**85**) is predicted to be more stable than the *trans* form (**86**) by 12–17 kJ mol<sup>-1</sup> by quantum chemical calculations. Tetramethylammonium peroxonitrite crystallizes in the *cis* form (**85**) (d(O=N) 116 pm, d(N–O) 135 pm, d(N–O) 141 pm)<sup>113</sup> and is nearly flat with a torsion angle of 22°. In a solid argon matrix, both conformers show a reversible photoisomerism.

Peroxonitrous acid is an acid of medium strength ( $pK_a = 6.8$ ), which rapidly decomposes in neutral conditions ( $t_{1/2} = 1$  s at pH = 7.4). Peroxonitrite can isomerize to nitrate or decompose to nitrite and dioxygen. Isomerization to nitrate is a major pathway in acidic media. The mechanism for the decomposition is still in doubt, but it is believed that HOONO homolyzes to give the NO<sub>2</sub>/OH radical pair.<sup>114</sup> Peroxonitrites are stable in basic solution. Peroxonitrous acid is formed as a yellow intermediate in the reaction of nitrite solutions with hydrogen peroxide that leads to nitrates.

It is a powerful oxidizing agent, stronger than nitric acid or hydrogen peroxide. The two-electron reduction potential of peroxonitrous acid is 1.68 V.

Tetramethylammonium *cis*-peroxonitrite, which decomposes at 383 K, is prepared by reacting tetramethylammonium superoxide with nitric oxide in liquid ammonia at 195 K.<sup>115</sup>

**Scheme 32** Isomers of peroxonitrite

Peroxonitrous acid reacts with azide to form dinitrogen oxide, nitrous acid, and N<sub>2</sub>.

It is believed that in biological systems NO reacts with superoxide O<sub>2</sub><sup>-</sup> to form the cytotoxic ONOO<sup>-</sup>. In biological media, low concentration levels of HCO<sub>3</sub><sup>-</sup> prevent the toxic effects of ONOO<sup>-</sup>, due to the formation of an unstable adduct with the composition ONO<sub>2</sub>CO<sub>2</sub><sup>-</sup>, which homolyzes to give the NO<sub>2</sub>/CO<sub>3</sub><sup>-</sup> radical pair.<sup>116</sup>

## 7.8 Nitric Acid

Pure, anhydrous nitric acid is a colorless liquid that fumes when exposed to air. Some of its physical properties are summarized in Table 29.<sup>4,5</sup>

The nitrate ion has a symmetrical, trigonal planar structure ( $D_{3h}$ , d(N–O) 121.8 pm, <(O–N–O) 120°). In nitric acid (**86**) ( $C_s$ ) (Figure 11), the N–O bond of the N–OH group with 140.5 pm is longer than the N–O bond lengths with 120.6 pm.

Nitric acid can be mixed with water in all proportions. It forms two hydrates, a monohydrate HNO<sub>3</sub>·H<sub>2</sub>O (m.p. 236 K), and a trihydrate HNO<sub>3</sub>·3H<sub>2</sub>O (m.p. 255 K). A third hydrate, the dihydrate HNO<sub>3</sub>·2H<sub>2</sub>O (m.p. 233 K) can be obtained by careful thermal treatment. In all three crystal structures, hydrogen bonds connect the oxygen atoms of planar NO<sub>3</sub><sup>-</sup> ions with pyramidal H<sub>3</sub>O<sup>+</sup> ions. In the monohydrate layers of hydrogen, bonded H<sub>3</sub>O<sup>+</sup> and NO<sub>3</sub><sup>-</sup> ions are formed, the other two hydrates have three-dimensional hydrogen-bonded networks. At a concentration of 69.2 wt%, nitric acid forms a maximum-boiling azeotrope with water with a boiling point

**Figure 11** Structure of the nitric acid

**Table 29** Physical properties of nitric acid

|                                                           |                     |                                                      |                                           |

| $\Delta H_f$ [kJ mol <sup>-1</sup> ]                      | -174.1 <sup>1</sup> |                                                      |                                           |

of 395 K.<sup>117</sup> The azeotropic mixture is known as concentrated nitric acid ( $\rho = 1.410 \text{ g cm}^{-3}$ ). Some physical properties of aqueous nitric acid in different concentrations are given in Table 30.

Nitric acid decomposes thermally in the reverse reaction of its formation:

In ambient light, this decomposition already takes place at room temperature so that pure nitric acid has to be stored at temperatures below 273 K. At 303 K, the equilibrium contains 98%  $\text{HNO}_3$ , at 323 K 89%  $\text{HNO}_3$ . The photodissociation of the nitrate anion in aqueous solution may proceed according to one of the following three paths:<sup>118</sup>

Decomposition occurs to the same extent for pathways (272) and (273), whereas path (273) is of very minor importance. No peroxonitrite is formed in a cage-recombination reaction of the products of (271). The oxygen anion of (271) reacts further with water to form hydroxyl radicals that can oxidize nitrite anions back to  $\text{NO}_2$ .

Reaction of the peroxonitrite  $\text{ONOO}^-$  anion with  $\text{OH}\cdot$  radicals from (274) forms the peroxonitrite radical  $\text{ONOO}\cdot$ , that decomposes to dioxygen and  $\text{NO}$ , the major source for the formation of nitrite ions  $\text{NO}_2^-$  in the system.

Dissolved nitrogen dioxide gives nitric acid a yellow color (fuming nitric acid). Higher concentrations of nitrogen dioxide give the nitric acid a red color (red fuming nitric acid). If the

oxygen produced is allowed to dissipate, even aqueous nitric acid solutions can decompose in this manner.

The chemistry of nitric acid is characterized by its acidity and oxidation strength. In dilute solutions of nitric acid, the acidity is more important for its chemical behavior, in concentrated nitric acid the oxidizing character dominates its chemical behavior.

Nitric acid is a strong acid ( $\text{p}K_a = -1.44$ ).

Dilute solutions of nitric acid are almost completely dissociated. In concentrated nitric acid, which dissociates according to (277), the nitracidium ion  $\text{H}_2\text{NO}_3^+$  is formed:

In the gas phase, two isomeric structures of the neutral radical  $\text{H}_2\text{NO}_3$  are found,<sup>119</sup>  $(\text{HO})_2\text{NO}$  and the more stable  $\text{H}_2\text{O}\cdot\text{NO}_2$ .  $\text{H}_2\text{NO}_3^+$ , which decomposes under elimination of water in analogy to the isoelectronic  $\text{H}_2\text{CO}_3$ :

$\text{H}_2\text{NO}_3^+$  is formed by adding a strong acid to nitric acid (279).

The decomposition of the nitracidium ion (278) shifts the dissociation equilibrium (276) to the right side.

The formation of nitronium ions  $\text{NO}_2^+$  and of water, that further reacts to

with a net equation of

explains the high electric conductivity ( $3.7210^{-2} \Omega \text{ cm}^{-1}$ ) of anhydrous nitric acid. These equilibria are also responsible for a rapid exchange of nitrogen atoms in nitric acid.

Nitrate has an oxidation potential of +0.96 V. Copper (+0.342 V) and silver (+0.799 V) are dissolved by nitric acid under formation of  $\text{NO}$  (which is instantly oxidized to  $\text{NO}_2$  in air), gold (+1.498 V) and platinum (+1.118 V) are not attacked. The oxidation of metals yields different products depending on the concentration of nitric acid. In

**Table 30** Physical properties of aqueous nitric acid as a function of composition

| 100                 | 1.5129                    | 232      | 359      |

dilute solutions of nitric acid, NO is formed, whereas in concentrated solutions, NO is oxidized by nitric acid to NO<sub>2</sub>. Moderately concentrated nitric acid oxidizes metals under formation of a mixture of NO and NO<sub>2</sub>. A 50% solution of HNO<sub>3</sub> (aqua fortis) is used to separate silver from gold. The oxidation power of nitric acid increases with increasing concentration. Dilute solutions of nitric acid do not attack copper and more noble metals.

Some metals (Al, Cr, and Fe) are not oxidized by concentrated nitric acid even though they would be expected to be oxidized based on their oxidation potentials. These metals form thin oxide layers that protect the metal core (passivation). As a result, alloyed steel equipment can be used in nitric acid technology.

In concentrated nitric acid, the NO<sub>2</sub><sup>+</sup> ion has the highest oxidation potential. Increasing its concentration increases the oxidizing power of nitric acid. This is commonly achieved by adding a strong acid, normally sulfuric acid:

The mixture of nitric acid and two parts of sulfuric acid is known as nitrating acid and is mainly used in organic chemistry for nitration reactions. In the mixture of one part nitric acid and three parts hydrochloric acid, NOCl and active chlorine (chlorine radicals) are formed:

This mixture dissolves almost all metals, even gold (aqua regia) but not niobium, tantalum, and tungsten.

In pure nitric acid, dissolved N<sub>2</sub>O<sub>4</sub> dissociates completely to NO<sup>+</sup> and NO<sub>3</sub><sup>−</sup>, and N<sub>2</sub>O<sub>5</sub> dissociates to NO<sub>2</sub><sup>+</sup> and NO<sub>3</sub><sup>−</sup>.

### 7.8.1 Production of Nitric Acid

Historically, nitric acid was synthesized by adding sulfuric acid to Chile salt-peter.<sup>5</sup>

The process of Birkeland and Eyde involved the direct combination of dinitrogen, dioxygen, and water ( $\Delta H = -30.3 \text{ kJ}$ ):

This reaction requires an electric arc to provide the high activation energy and is therefore quite expensive. The availability of cheap ammonia synthesized by the Haber–Bosch process signaled the demise of this process.

Today, nitric acid is produced by the Ostwald process, which involves three chemical steps:

First, ammonia is catalytically oxidized to nitric oxide with atmospheric oxygen ( $\Delta H = -904 \text{ kJ mol}^{-1}$ ):

This is one of the most efficient catalytic processes known. With a suitable catalyst, 93–98% of ammonia is oxidized to NO. Side reactions include the formation of dinitrogen oxide ( $\Delta H = -1105 \text{ kJ mol}^{-1}$ ) (289) and the formation of dinitrogen (290) ( $\Delta H = -1268 \text{ kJ mol}^{-1}$ ).

Decomposition of the formed NO (291) ( $\Delta H = -90 \text{ kJ mol}^{-1}$ ) and its reaction with ammonia (292) ( $\Delta H = -1808 \text{ kJ mol}^{-1}$ ) also occur:

A short reaction time (in the order of  $10^{-3} \text{ s}$ ) is necessary to avoid the decomposition of the metastable NO according to (291). Closely stacked, fine mesh gauzes of platinum, usually alloyed with 5–10% of rhodium to improve its mechanical strength, are used as catalysts. The loss of precious metal catalysts has a significant effect on the operating costs, therefore great efforts are made to recover the catalyst loss by filters and recovery gauzes. In the technical process, a 1:10 mixture of ammonia and oxygen is pressed at high velocity at temperatures between 973 K and 1223 K and pressures between 0.1 and 1.2 MPa through the catalyst gauzes.

The nitrogen oxide gas is then cooled down and, if necessary, compressed. Here the nitrogen oxide is partly oxidized by the dioxygen in air to NO<sub>2</sub> (293) ( $\Delta H = -113.6 \text{ kJ mol}^{-1}$ ), which dimerizes to N<sub>2</sub>O<sub>4</sub> (294) ( $\Delta H = -58.08 \text{ kJ mol}^{-1}$ ):

Dinitrogen trioxide is also formed ( $\Delta H = -40 \text{ kJ mol}^{-1}$ ):

The absorption of this complex mixture of gases and the formation of nitric acid follows a complicated mechanism. The main route involves two steps in the liquid phase. First, dinitrogen tetroxide reacts with water to form nitric acid and nitrous acid ( $\Delta H = -87 \text{ kJ mol}^{-1}$ ):

Nitrous acid then disproportionates to nitric acid and NO ( $\Delta H = -15.3 \text{ kJ mol}^{-1}$ ), which again enters the oxidation process.

Absorption is normally performed in plate columns. Nitrogen monoxide is constantly reformed in this step and prevents the complete absorption of the inlet gases. Oxidation of nitrogen monoxide mainly occurs in the gas phase between the plates, but also in the bubble layer on the plates. The absorption efficiency increases at lower temperatures (higher  $\text{N}_2\text{O}_4$  concentration) and higher pressures. Temperatures of 293 to 303 K and pressures of 5–10 MPa are used. The emission of nitrous gases is an environmental problem, which led to the design of advanced absorption towers and the development of different scrubbing processes for the stack gas. Nitric acid produced in technical processes has concentrations of 50–70%, depending on the absorption process. This is enough for most uses, including the production of fertilizers. Some processes require 100% nitric acid, which cannot be obtained by distillation because of the formation of an azeotropic mixture with water containing 68.4%  $\text{HNO}_3$ . Greater concentrations are obtained in a direct process by reacting liquid dinitrogen under pressure with pure oxygen and a certain quantity of dilute nitric acid. In an indirect process, either sulfuric acid or magnesium nitrate is added to commercial nitric acid. Distillation of these mixtures yields 99% nitric acid.

The principal use of nitric acid is the production of fertilizers, which uses between 75 and 85% of the total nitric acid production. Further uses include the production of organic nitro compounds that are used as explosives and rocket fuels. In 1987, 26.5 megatons of nitric acid were produced worldwide.

### 7.8.2 Nitrates

The reaction of nitric acid with metal oxides, hydroxides, or carbonates yields metal nitrates.<sup>5</sup> Hydrogendinitrates  $\text{H}(\text{NO}_3)_2^-$  and dihydrogentrinitrates  $\text{H}_2(\text{NO}_3)_3^-$  that contain nitrogen ions bound by hydrogen bonds are also known.  $\text{H}(\text{NO}_3)_2^-$  has a symmetrical hydrogen bond between the nitrate ions with an O–O distance of 245 pm, the hydrogen bonds in  $\text{H}_2(\text{NO}_3)_3^-$  are asymmetrical with O–O distances of 260 pm. Nitrates of the alkali and alkaline-earth metals as well as ammonium nitrate contain discrete  $\text{NO}_3^-$  ions; transition metal nitrates show a coordinative bond to the nitrate group. All nitrates dissolve readily in water. Heating results in decomposition under elimination of dioxygen. Alkali and alkaline-earth nitrates form nitrites, heavy metal nitrites form oxides and  $\text{NO}_2$ .

For the complex decomposition processes of ammonium nitrate, see section ‘Ammonium Nitrate’.

Alkali metal nitrates have comparatively low-melting points and the solid nitrates are excellent oxidizers at higher temperatures. Potassium nitrate is used as an oxidizer in black powder (75 wt%  $\text{KNO}_3$ , 15% charcoal, 10% sulfur). Fertilizer mixtures commonly contain ammonium nitrate or potassium nitrate, sometimes sodium or calcium nitrate as nitrogen compounds. Ammonium nitrate is also used as an explosive or as an oxidizer in an explosive mixture. Some properties of important nitrate fertilizers are summarized in Table 31.

In nitrate complexes, the nitrate ligand is found in the different coordination modes shown in Scheme 33:

### 7.9 Orthonitrates

Free orthonitric acid  $\text{H}_3\text{NO}_4$ , which would be analogous to  $\text{H}_3\text{PO}_4$ , has not been observed yet. The salts of orthonitric acid, the orthonitrates, contain tetrahedral  $T_d$   $\text{NO}_4^{3-}$  ( $d(\text{N}-\text{O})$  139 pm) with somewhat smaller N–O distances than expected for N–O single bonds.<sup>120</sup>

Sodium orthonitrate is prepared by the reaction of sodium nitrate and sodium oxide at 573 K for one week:<sup>100</sup>

Water decomposes the orthonitrate ion to nitrate:

The orthonitrates, for example, sodium orthonitrate, readily react with atmospheric water vapor and carbon dioxide:

### 7.10 Peroxonitric Acid

In the reaction of pure hydrogen peroxide with dinitrogen pentoxide at 195 K, peroxonitric acid is formed:

Peroxonitric acid is very unstable<sup>121</sup> and decomposes explosively at temperatures above 243 K. It has a  $pK_a$  of

**Table 31** Properties of important nitrate fertilizers

**Scheme 33** Coordination modes of nitrate ligands

5.9, which is similar to the  $\text{pK}_a$  of peroxonitrous acid of 6.8. In dilute solutions, peroxonitric acid can be stored for a short time at 293 K. In contrast to peroxonitrous acid, which is stable in basic solution and decomposes in acidic solution, peroxonitric acid is relatively stable at moderate to low pH. Under these conditions, a slow N–O bond cleavage reaction gives the  $\text{OOH}/\text{NO}_2$  radical pair. If peroxonitric acid is diluted too much, it hydrolyzes to form hydrogen peroxide and nitric acid. At a pH higher than 5, peroxonitrates decompose rapidly as follows:

The decomposition either follows homolysis, initially to  $\text{NO}_2/\text{O}_2^-$ , or heterolysis, initially to  $^1\text{O}_2/\text{NO}_2^-$ . In contrast to peroxonitrous acid, peroxonitric acid is insensitive to the presence of  $\text{CO}_2$ . Peroxonitric acid is a strong oxidizer with a two-electron reduction potential of 1.83 V.

### 7.11 Nitrosamine

$\text{NH}_2\text{NO}$  is a transient intermediate in the reaction,

which is part of the deNO<sub>x</sub> process. In the deNO<sub>x</sub> process, nitrogen oxides are reduced to dinitrogen with either ammonia or urea. The process works both catalytically (SCR, selective catalytic reduction) or noncatalytically (SNCR, selective non-catalytic reduction). In the noncatalytic process, temperatures have to be between 1025 and 1300 K, at lower temperatures the reduction does not work. The noncatalytic process follows a radical mechanism. In the catalytic process, lower temperatures between 473 and 573 K are sufficient. Titanium oxide catalysts are used with promoter oxides like  $\text{V}_2\text{O}_5$ . The process is used in large industrial plants and for diesel engines.

Depending on the composition of the exhaust, different reactions occur:

Under the reaction conditions in the NO<sub>x</sub> removal process,  $\text{H}_2\text{NNO}$  is very short-lived because it is formed in a vibrationally excited state. The highly carcinogenic organic derivatives of nitrosamine  $\text{R}_2\text{NNO}$  are more stable and can be isolated in bulk.

### 7.12 Nitramide

Nitramide<sup>122</sup> (**87**) is a structural isomer of hyponitrous acid  $\text{HON}=\text{NOH}$  ( $\text{H}_2\text{N}_2\text{O}_2$ ) (Figure 12).

It is a colorless solid, which melts in the range of 354–359 K. In a dry environment, it is stable up to 393 K, in the presence of moisture the decomposition may begin at 343 K.

The N–N bond in nitramide is shorter than a typical N–N single bond (145 pm in hydrazine) (see Table 32). The N–O bonds are also shorter than typical N–O single bonds. Both bonds have a greater bond order than one. In the solid state, hydrogen bonds connect the NH hydrogen atoms to

**Figure 12** Lewis structure of nitramide

the oxygen atoms of the nitro group of another molecule, building a structure of hydrogen-bonded nitramide molecules. This hydrogen bonding results in a planar structure and a shorter N–N bond length in the solid phase. In the gas phase, the amino and nitro groups are twisted.

Aqueous solutions of nitramide are slightly acidic ( $pK_a = 6.6$ ). The nitramide anion is not stable in salts, and the sodium, potassium, and ammonium salts decompose in solution. Nitramide, like hyponitrous acid, decomposes slowly forming  $N_2O$  and water. The decomposition is base-catalyzed and proceeds faster with stronger bases  $OR^-$ ,

thus giving the overall reaction:

The nitramide anion  $O_2NNH^-$  can rearrange to imidonitric acid  $HNN(OH)O^-$ , which in turn decomposes to  $N_2O$ . In mildly acidic solution, the decomposition is nonetheless base-catalyzed with water acting as a base.

Nitramide can be prepared by the decomposition of potassium nitrocarbamate in an acidic medium:

Other preparations include the hydrolysis of nitrocarbamic acid (316), the reaction of  $NaSO_3NH_2$  with concentrated nitric acid, (317) and the reaction of  $N_2O_5$  with two equivalents of ammonia (318) (see Scheme 34).

### 7.13 Dinitramic Acid

Dinitramic acid<sup>123</sup> (**88**) and the dinitramide anion were discovered in 1971 (Figure 13). However, it was then only known in the former Soviet Union and was independently discovered in the United States in 1989.

In the gas phase, the dinitramide ion  $N(NO_2)_2^-$  has  $C_s$  symmetry. In the solid state, the symmetry is often distorted by interactions with the counterion, for example, hydrogen bonding with the ammonium ion in ammonium dinitramide (see Table 33). The N– $NO_2$  rotation barrier is very low. In fact, though the bond lengths of the nitramide ion remain fairly constant, no two-dinitramide crystal structures show the same geometry of the dinitramide anion.<sup>124</sup> The crystal structure of lithium dinitramide shows the symmetric anion.

**Figure 13** Lewis structure of dinitramic acid**Scheme 34** Reactions of  $N_2O_5$  with ammonia

The N–N bonds of dinitramide are shorter than N–N single bonds (145 pm in N<sub>2</sub>H<sub>4</sub>).

Dinitramic acid (**88**) is a strong acid ( $pK_a = -5.62$ ). Aqueous solutions of dinitramic acid with a concentration of 7–10% can be safely and easily prepared by passing a solution of KN(NO<sub>2</sub>)<sub>2</sub> through a protonated ion-exchange resin. A nonaqueous solution is obtained by passing HCl through a suspension of KN(NO<sub>2</sub>)<sub>2</sub> in ether at 273–278 K. Removal of ether yields a viscous yellow liquid that still contains some ether and is very shock and heat sensitive. After removal of the solvent at 273 K, dinitramic acid decomposes, often explosively, to a mixture of nitrogen oxides. Slow decomposition in air results in nitric acid as the major product. Solutions of dinitramic acid, either in water or in organic solvents, can be stored without noticeable decomposition if their concentration is less than 20%. The dinitramide anion is stable in the pH range 0–15. In concentrated acids, the dinitramide anion decomposes slowly at room temperature.

Solutions of dinitramic acid can be used to synthesize dinitramide salts with metal hydroxides, carbonates or oxides, and the salts of amine bases:

The metal dinitramides are crystalline substances that are generally stable at 298 K and have low-melting points. They are usually nicely soluble in water, alcohols, acetonitrile, and other polar solvents. Heavy metal dinitramides like silver dinitramide are sensitive to friction. Silver dinitramide is used in metathesis reactions with halides to produce dinitramide salts.

### 7.13.1 Ammonium Dinitramide

Ammonium dinitramide ( $\rho = 1.82 \text{ g cm}^{-3}$ ,  $\Delta H_f = 148(10) \text{ kJ mol}^{-1}$ ) is a colorless solid with a melting point of 365 K. The four hydrogen atoms of the ammonium ion form hydrogen bonds to oxygen atoms of surrounding dinitramide ions ( $d(\text{N}–\text{O})$  215.3 to 223.0 pm). These tetrahedrally arranged hydrogen bonds set up a three-dimensional network of hydrogen bonds. Slow decomposition of ammonium

dinitramide begins above the melting point. The salt decomposes, often explosively, at 408 K. Like many other ammonium salts, the first step in the volatilization ( $\Delta H_{\text{sub}}$  between 125 and 185 kJ mol<sup>-1</sup>,  $\Delta H_{\text{fusion}} = 130 \text{ kJ kg}^{-1}$ ) of ammonium dinitramide is proton transfer from the ammonium NH<sub>4</sub><sup>+</sup> cation to the dinitramide anion N(NO<sub>2</sub>)<sub>2</sub><sup>-</sup>, to form a hydrogen-bonded acid base pair (NH<sub>3</sub>·HN(NO<sub>2</sub>)<sub>2</sub>).

Depending on the temperature, ammonium dinitramide can then decompose in two different ways. At temperatures between 328 K and 373 K, N<sub>2</sub>O is eliminated from the molecule:<sup>125</sup>

Above 383 K, the favored decomposition pathway produces NO<sub>2</sub> in a homolytic bond fission reaction:

HNNO<sub>2</sub> further decomposes to N<sub>2</sub>O and OH or NH and NO<sub>2</sub>. The decomposition to N<sub>2</sub>O is slow, whereas the decomposition forming NO<sub>2</sub> is rapid.

Ammonium dinitramide can be obtained in low yields of 13–30% by the nitration of ammonia with N<sub>2</sub>O<sub>5</sub>, and extraction of the solid products with ethyl acetate. The main product of this reaction is ammonium nitrate. Nitramide or ammonium dinitramide can be obtained by careful control of the reaction conditions (see Scheme 34).

Organic dinitramines of the type RCH<sub>2</sub>CH<sub>2</sub>N(NO<sub>2</sub>)<sub>2</sub> with an electron accepting group (R = CN, CHO, COR, COOR, or NO<sub>2</sub>) eliminate ammonium dinitramide and acrylic compounds H<sub>2</sub>C=CHR during decomposition in aqueous solutions of ammonia.

The nitration of deactivated amines H<sub>2</sub>NR (R = NO<sub>2</sub>, OOCCH<sub>2</sub>H<sub>5</sub>, H<sub>4</sub>NO(O)C, H<sub>4</sub>NOS(O)<sub>2</sub>, H<sub>2</sub>NCO) with strong nitrating agents (N<sub>2</sub>O<sub>5</sub>, NO<sub>2</sub>BF<sub>4</sub>, O<sub>2</sub>NS<sub>2</sub>O<sub>7</sub>H, HNO<sub>3</sub>/SO<sub>3</sub>/H<sub>2</sub>SO<sub>4</sub>) and neutralization of the reaction mixture with ammonia or aqueous solutions of ammonia also yields ammonium dinitramide.

All nitration reactions are highly exothermic and require temperatures below 273 K to achieve good yields and to avoid decomposition of ammonium dinitramide to gaseous products and ammonium nitrate.

Current research aims to establish ammonium dinitramide as a replacement for ammonium perchlorate as an oxidizer

**Table 34** Properties of nitrogen halides

|                               | F                                                                                                                      | Cl                                                                                        | Br                                                                             | I                                                                           |

in rocket propellants and other explosive formulations to avoid the environmental problem of chlorine emission. Unfortunately, ammonium dinitramide is thermally and mechanically more sensitive than ammonium perchlorate.

Hydroxylammonium dinitramide is not stable at ambient conditions. However, a salt with the formula (H<sub>3</sub>NOH)<sub>2</sub>[N(NO<sub>2</sub>)<sub>2</sub>]·2H<sub>2</sub>NOH is known. All hydroxylamine species in this salt are involved in hydrogen bonding, and one of the coordinated hydroxylamine molecules shows zwitterionic behavior. The salt resembles the formula (H<sub>3</sub>NOH)<sub>2</sub>[N(NO<sub>2</sub>)<sub>2</sub>]·H<sub>2</sub>NOH·H<sub>3</sub>N<sup>+</sup>O<sup>−</sup>. Hydrazinium dinitramide (N<sub>2</sub>H<sub>5</sub>)<sub>2</sub>[N(NO<sub>2</sub>)<sub>2</sub>] also has a three-dimensional hydrogen bond network, but is less stable than ammonium dinitramide.

## 8 NITROGEN HALIDES

The properties of nitrogen halides are summarized in Table 34.

### 8.1 Nitrogen Fluoride compounds

All NCl, NBr, and NI compounds are thermodynamically unstable ( $\Delta H_f > 0$ ). Some, but not all binary NF compounds are exothermic species, with NF<sub>3</sub> as the most stable species. During the 1960s, NF compounds were investigated as rocket propellants. Today, NF compounds are used in chemical lasers and as high-energy density materials, but no compound

has achieved widespread use.<sup>126,127</sup> The bonding situation in nitrogen fluorides is explained in the literature.<sup>128</sup> The N–F bond lengths are given in Table 35, the other bonding parameters in Table 36.

#### 8.1.1 Fluoramine

Fluoramine is synthesized by vaporizing the adduct NH<sub>2</sub>F·2HF (NH<sub>3</sub>F<sup>+</sup> HF<sub>2</sub><sup>−</sup>) in a dynamic vacuum. The reaction gas is passed through activated, powdered KF to absorb HF and is collected at 76 K.<sup>126</sup>

**Table 35** N–F bond lengths in binary N–F compounds

Above 173 K fluoramine decomposes:

As a weak base, fluoramine reacts with strong acids HX (X e.g. HF<sub>2</sub><sup>–</sup>, SO<sub>3</sub>F<sup>–</sup>, ClO<sub>4</sub><sup>–</sup>, and HSO<sub>4</sub><sup>–</sup>) forming fluorammonium salts NH<sub>3</sub>F<sup>+</sup>X<sup>–</sup>. The stability of the NH<sub>3</sub>F<sup>+</sup> salts is influenced by the acidity of the anion and increases in the order SO<sub>3</sub>Cl<sup>–</sup> < ClO<sub>4</sub><sup>–</sup> < H<sub>3</sub>CSO<sub>3</sub><sup>–</sup> < SO<sub>3</sub>F<sup>–</sup> < F<sub>3</sub>CSO<sub>3</sub><sup>–</sup>.

### 8.1.2 Difluoramine

Difluoramine has a melting point of 156.6 K and a boiling point of 249.4 K. The boiling point is considerably higher than the boiling point of NF<sub>3</sub> (144.2 K) due to hydrogen bonding in the liquid.<sup>130</sup> It is an unstable compound that requires very careful handling since it often explodes spontaneously, especially on freezing or melting.<sup>126</sup>

Difluoramine can be obtained by the hydrolysis of *N,N*-difluorourea with concentrated sulfuric acid.

Other preparations include the hydrolysis of *N,N*-difluorosulfamide (F<sub>2</sub>NSO<sub>2</sub>NH<sub>2</sub>) or trityldifluoramine ((C<sub>6</sub>H<sub>5</sub>)<sub>3</sub>CNF<sub>2</sub>).

Anhydrous difluoramine decomposes thermally (in the presence of KF as HF absorber) to dinitrogen difluoride.

Difluoramine is a versatile reagent in organic synthesis and is used, among others, to synthesize organic difluoramino and geminal bis(difluoramino) derivatives of organic compounds. Reaction of NHF<sub>2</sub> with ClF at low temperatures leads to chlorodifluoramine.

Reaction of difluoramine with ClO<sup>–</sup> also yields chlorodifluoramine NF<sub>2</sub>Cl, and reaction with bromine yields bromodifluoramine NF<sub>2</sub>Br.

Difluoramine is a weak base that can form adducts with Lewis acids (BF<sub>3</sub>, BCl<sub>3</sub>, PF<sub>5</sub>, SO<sub>2</sub>) that are formed at 195 K and decompose well below ambient temperature. NHF<sub>2</sub> reacts with AsF<sub>5</sub> in anhydrous HF below 195 K to NH<sub>2</sub>F<sub>2</sub><sup>+</sup> AsF<sub>6</sub><sup>–</sup>. Otherwise difluoramine reacts as an acid:

In the absence of other reaction partners the difluoroamide anion reacts to form *cis/trans*-N<sub>2</sub>F<sub>2</sub>.

Fe<sup>3+</sup> oxidizes NF<sub>2</sub><sup>–</sup> to tetrafluorohydrazine.

### 8.1.3 Nitrogen Trifluoride

Nitrogen trifluoride is a colorless, odorless gas with a boiling point of 144.2 K and a melting point of 66.4 K. It has a trigonal pyramidal structure with a F–N–F angle of 102.1°. The dipole moment of NF<sub>3</sub> (0.2340 D) is lower than the dipole moment of ammonia (1.47 D), which can be explained by the reversed polarity of nitrogen. NF<sub>3</sub> has a positively polarized nitrogen atom and the dipole moment of the lone pair is in opposite direction to the dipole moment along the same axis associated with the three N–F bonds. In ammonia, the polarities are reversed and the dipole moments, of the NH bonds and the lone pair operate in the same direction. Compared to other fluoramines, the N–F bond in NF<sub>3</sub> is relatively short (see Table 35). This can be explained by an electrostatic model. The partial charges in NF<sub>3</sub> (N<sup>δ+</sup> F<sup>δ–</sup>) indicate a strong attractive interaction, a weak attraction in HNF<sub>2</sub>, and a repulsive electrostatic interaction (N<sup>δ–</sup> F<sup>δ–</sup>) in H<sub>2</sub>NF.<sup>126,127</sup>

NF<sub>3</sub> is synthesized by the melt electrolysis of NH<sub>4</sub>F/HF mixtures, or by the fluorination of ammonia catalyzed by copper.

At low temperatures, NF<sub>3</sub> reacts only sluggishly, giving no reaction with H<sub>2</sub>, CO, CH<sub>4</sub>, H<sub>2</sub>S and many other compounds. Although these reactions are in fact thermodynamically favored, they are prevented at ambient temperatures by the kinetic stability of NF<sub>3</sub>. When the activation energy is provided by heating or an electric spark, NF<sub>3</sub> reacts readily and sometimes explosively.

At higher temperatures, NF<sub>3</sub> reacts with metals (e.g. Li, Na, K, Cu, Ag, Mg, Ca, Ba, Zn, Cd, Hg, Sn, Pb) and nonmetals (e.g. H<sub>2</sub>, B, Si, As, Sb) to form fluorides. In the reaction with the metals Bi, Sb, Cu, or As in a flow reactor, the metals are converted to the respective fluorides and NF<sub>3</sub> is reduced to tetrafluorohydrazine.

After ignition with a spark, the reaction with dihydrogen proceeds with a sharp bang and a red-violet glow (see **Hydrogen: Inorganic Chemistry**). Ignition of a mixture of NF<sub>3</sub> and water vapor gives a slow reaction that is accompanied by a blue glow, and leads to hydrogen fluoride and nitrous acid. At room temperature, NF<sub>3</sub> does not react with water.

NF<sub>3</sub> shows low inclination toward coordination and is a poor ligand.

The reaction of NF<sub>3</sub> with AsF<sub>5</sub>, SbF<sub>5</sub> or BF<sub>3</sub>, and fluorine leads to salts of the tetrahedral NF<sub>4</sub><sup>+</sup> ion (d(N–F) 130 pm).

NF<sub>4</sub><sup>+</sup> is one of the strongest fluorinating agents known.

Metathesis reactions that form CsSbF<sub>6</sub>, which is almost insoluble in HF, can be used to obtain different NF<sub>4</sub><sup>+</sup> salts.

NF<sub>4</sub><sup>+</sup> HF<sub>2</sub><sup>−</sup> cannot be obtained in a pure form, as it always contains some HF. It decomposes at room temperature to form NF<sub>3</sub>, F<sub>2</sub>, and HF. The HF solution of this salt is stable at room temperature. Theoretical calculations indicate that a hypothetical NF<sub>5</sub> has a decomposition barrier of 69 kJ mol<sup>−1</sup> but so far no experimental evidence has been found for this

species.<sup>131</sup> For more information on hypervalent compounds, see **Hypervalent Compounds**.

In the thermal decomposition of NF<sub>4</sub><sup>+</sup>H<sup>18</sup>F<sub>2</sub><sup>−</sup>, the fluorine atom of HF<sub>2</sub><sup>−</sup> only attacks fluorine atoms and not the central nitrogen atom.

#### 8.1.4 Tetrafluorohydrazine

Tetrafluorohydrazine is a colorless gas with a melting point of 108.7 K and a boiling point of 200 K. The structure of tetrafluorohydrazine (microwave: d(N–N) 140(2) pm, d(N–F) 135 pm, <(F–N–F) 107(2)°, electron diffraction: d(N–N) 148(2) pm, d(N–F) 139(1) pm, <(F–N–F) 103.0(1)°) resembles hydrazine. In the temperature range of 123–193 K, the staggered (C<sub>2h</sub>) and gauche (C<sub>2</sub>) isomers of tetrafluorohydrazine are in equilibrium both in the condensed phase and the vapor phase. The staggered conformation is favored by about 2 kJ mol<sup>−1</sup> and a barrier of 12.5 kJ mol<sup>−1</sup> hinders the free rotation of the NF<sub>2</sub> groups. N<sub>2</sub>F<sub>4</sub> is synthesized by fluorine abstraction from NF<sub>3</sub> with metals, or by the oxidation of difluoramine with an alkaline solution of hypochlorite.<sup>126</sup>

Tetrafluorohydrazine is a strong fluorinating agent.

Tetrafluorohydrazine has a long and weak nitrogen–nitrogen bond and dissociates easily into deep blue ·NF<sub>2</sub> radicals (d(N–F) 136.3 pm, <(F–N–F) 102.5°).

The easy dissociation (K = 0.03 at 43 K, ΔH° = 83.2 kJ mol<sup>−1</sup>) into radicals explains the higher reactivity of N<sub>2</sub>F<sub>4</sub> compared to NF<sub>3</sub>. Reaction of N<sub>2</sub>F<sub>4</sub> with chlorine yields chlorodifluoramine. In the reaction with NO, the purple, easily dissociating nitrosodifluoramine NF<sub>2</sub>NO is formed and reaction with S<sub>2</sub>F<sub>10</sub> yields the colorless NF<sub>2</sub>SF<sub>5</sub>.

The highly unstable F<sub>2</sub>NNO<sub>2</sub> is formed in the reaction with NO<sub>2</sub> at 583 K and rapid quenching at 77 K.

**Scheme 35**  $N_2F_4$  isomers

Tetrafluorohydrazine is used for the synthesis of organic compounds containing the  $-NF_2$  or  $=NF$  group, for example, it adds to olefines.

The reaction of tetrafluorohydrazine with strong fluorine acceptors ( $AsF_5$ ,  $SbF_5$ ) forms salts of the planar  $C_s$  cation  $N_2F_3^+$ .<sup>132</sup>

### 8.1.5 Difluorodiazene

Two planar isomers of  $N_2F_2$  are known (Scheme 35), the *cis* (**89**) ( $C_{2v}$ , m.p.  $<78$  K, b.p.  $167.3$  K,  $\mu$   $0.18$  D) and *trans* isomers (**90**) ( $C_{2h}$ , m.p.  $101$  K, b.p.  $161.8$  K,  $\mu$   $0$  D).<sup>126</sup> Their bonding parameters are given in Table 37.

The shortening of the N–N bond in the *cis* isomer (**89**), which is accompanied by a lengthening of the N–F bond, can be explained by negative hyperconjugation. This corresponds to the partial delocalization of the nitrogen lone pair into the antibonding  $\sigma^*$  orbital of the neighboring N–F group. This donor–acceptor interaction is only present in the *cis* isomer. The *cis* isomer (**89**) is thermodynamically favored by  $13 \text{ kJ mol}^{-1}$ . At  $298$  K, the equilibrium has about 90% *cis* and 10% *trans*, and at about  $342$  K the *trans* isomer (**90**) rearranges to the *cis* form (**89**). At  $570$  K,  $N_2F_2$  dissociates to the elements. The equilibrium is only slowly attained at lower temperatures without catalysts. Therefore, the pure isomers of  $N_2F_2$  can be obtained.

The two isomers react very differently. The *cis* form is more stable as well as more reactive. The *trans* form can be stored in glass vessels, whereas the *cis* form reacts slowly with glass to form  $SiF_4$  and  $N_2O$ .

Dinitrogen difluoride is best synthesized by passing difluoramine over KF.

**Table 37** Bonding parameters of  $N_2F_2$  compounds

|                              | <i>cis</i> | <i>trans</i> |
|------------------------------|------------|--------------|
| $d(N-F)$ [pm]                | 140.9      | 139.8        |
| $D(N-N)$ [pm]                | 120.9      | 122.4        |
| $\angle(F-N-N)$ [ $^\circ$ ] | 114        | 106          |

**Figure 14** Lewis structure of the  $N_2F^+$  cation

The thermal decomposition of fluorine azide also yields  $N_2F_2$ .

These preparations, as well as the reaction of nitrogen trifluoride with mercury vapor in an electric discharge, and the fluorination of sodium azide yield mixtures of both isomers. The pure *trans* isomer is produced in 45% yield by the reaction of tetrafluorohydrazine with aluminum trichloride, or by the reaction of a mixture of the  $N_2F_2$  isomers with aluminum trichloride.

Only the *cis* isomer reacts with  $AsF_5$  to form the linear fluorodiazanium ion  $N_2F^+$  (**90**) in Figure 14 that has the shortest known N–F bond ( $d(N-F)$   $122$  pm,  $d(N-N)$   $109.9$  pm).  $N_2F^+$  is isoelectronic to  $NO_2^+$ .<sup>133</sup>

In the reaction of  $N_2F^+$  (**91**) with NaF and HF, only *cis*- $N_2F_2$  is formed.

Heating a mixture of  $FN_3$  and  $ClN_3$  to  $393$  K results in a yellow, highly explosive substance that has not been isolated so far. It is assumed to be  $ClNNF$ .<sup>134</sup>

## 8.2 Nitrogen Chlorides

### 8.2.1 Chloramine

Chloramine has a melting point of  $203$  K. Decomposition begins at  $163$  K, and above  $233$  K the decomposition is explosive. Gaseous  $NH_2Cl$  at low pressures and dissolved  $NH_2Cl$  at low concentrations are thermally slightly more stable.  $NH_2Cl$  is readily soluble in water and ether, but less soluble in  $CHCl_3$  and  $CCl_4$ . In aqueous solution, it decomposes according to (360):

This decomposition occurs in a neutral, or mildly alkaline (up to pH = 11) medium. The reaction is slow, only a few percent of a 0.1 M solution of  $\text{NH}_2\text{Cl}$  in water decompose according to (360) in several weeks. At pH values above 11, the equilibrium for the synthesis (365) is shifted to the hypochlorite side and the following reaction slowly occurs:

In an acidic medium at pH values of around 4, chloramine disproportionates to form dichloramine (362), which in turn disproportionates at pH values below 3 (363), so that at low pH values,  $\text{NCl}_3$  dominates and between pH 3–5  $\text{NHCl}_2$  dominates.

These equilibria are disturbed by the irreversible decomposition of  $\text{NHCl}_2$  and  $\text{NCl}_3$ :

In dilute aqueous solution, chloramine is prepared by the reaction of ammonia with sodium hypochlorite:

As a result of the decomposition reactions shown above, the reaction has to be carried out in a slightly alkaline medium (pH = 8.5 to 11). This is also the first step of the Raschig hydrazine synthesis. The acting chlorinating agent in this reaction is hypochlorous acid  $\text{HOCl}$ , which has to be generated by protonation of hypochlorite, and then reacts in a nucleophilic substitution of the hydroxo against the amino group. The reaction occurs quickest at around pH = 8, at higher pH values the concentration of hypochlorous acid is lower, at lower pH values ammonia  $\text{NH}_3$  is protonated to form ammonium ions  $\text{NH}_4^+$ , which do not react further. The  $\text{NH}_2\text{Cl}$  solutions can be concentrated by vacuum distillation, and passing the vapor through potassium carbonate which absorbs the water.  $\text{NH}_2\text{Cl}$  can be extracted with ether. Gaseous chloramine can be obtained from the reaction of gaseous ammonia with chlorine gas that is diluted with nitrogen gas in molar ratios of 20:1 to 6:1.<sup>135</sup>

By passing the effluent from the gas-phase reaction into a solvent at 253 K and then removing the ammonia by warming up the solution or passing it through a column with anhydrous copper(II) sulfate, solutions of chloramine in various solvents can be obtained. Almost pure (97%)  $\text{NH}_2\text{Cl}$  is obtained by the fractional low-temperature condensation of the effluent. Pure

$\text{NH}_2\text{Cl}$  is synthesized by passing pure fluoramine through a layer of  $\text{CaCl}_2$ :

Chloramine is both a very weak base and a very weak acid ( $\text{p}K_a = 14$ ,  $\text{p}K_b = 15$ ). In water  $\text{NH}_2\text{Cl}$  acts neutral. It is an oxidizing agent (acidic solution:  $E^\circ = -1.48 \text{ V}$ , in basic solution  $E^\circ = -0.81 \text{ V}$ )

Reactions of chloramine include radical, nucleophilic, and electrophilic substitution of chlorine, electrophilic substitution of hydrogen, and oxidative additions, for example:

Chloramine can, like  $\text{HOCl}$ , donate positively charged chlorine  $\text{Cl}^+$  in reactions with nucleophiles  $\text{Nu}^-$ .

These reactions follow the  $\text{S}_{\text{N}}2$  mechanism at the chlorine atom of  $\text{NH}_2\text{Cl}$  or  $\text{NH}_3\text{Cl}^+$ . An example is the chlorination of the hydroxide ion  $\text{OH}^-$  in highly alkaline solution (reverse of (365)).

Another chlorination is the reaction of chloramine to form dichloramine, which starts the decomposition in an acidic medium.

This equilibrium lies to the left side under normal conditions, but can be shifted to the right side by removing ammonia, for example, by protonation. Hydrazine is chlorinated in acidic solution:

Chlorohydrazine, like all chloro-, bromo- or iodohydrazines, is not stable and immediately decomposes to diimine,

which in turn disproportionates to dinitrogen and hydrazine.

The overall equation of the reaction of chloramine with hydrazine is as follows (Raschig process, see Section 5.2.1):

Nucleophiles can also react according to an  $S_N2$  mechanism at the nitrogen atom. This is an amination reaction, where the  $NH_2^+$  group is transferred to the nucleophile.

The reaction is also called electrophilic amination and amino donors like  $NH_2Cl$  or  $NH_2OSO_3H$  are called electrophilic amination agents.

The amination of ammonia with chloramine to form hydrazine is an example of this mechanism (Raschig process):

This reaction can also be carried out with substituted amines  $RNH_2$ ,  $R_2NH$ , and  $R_3N$  to form the corresponding substituted hydrazines  $RNH-NH_2$ ,  $R_2NH-NH_2$ , or  $R_3N^+-NH_2$  salts.

Chloramine electrophilically aminates itself in neutral and alkaline media to start its decomposition.

Chlorohydrazine decomposes as described above (374), the net reaction of this decomposition is given by equation (360).

Hydrazine can also be aminated by chloramine, but only in alkaline solution:

In acidic solution, the chlorination to form chlorohydrazine (373) is much faster. Triazanium chloride is only stable at temperatures below 223 K, otherwise it decomposes under cleavage of  $NH_4Cl$  to diimine.

In turn, diimine disproportionates according to (375), thus giving an overall equation that is identical to the reaction in the acidic medium (376):

The reaction of chloramine with *N,N*-disubstituted hydrazines  $R_2NNH_2$  yields stable triazanium salts:

In the reaction of  $(CH_3)_2NNH_2$  with chloramine,  $(CH_3)_2NN=CH_2$  and  $(CH_3)_2NN=NN(CH_3)_2$  were found as side products, indicating the intermediate formation of dimethyldiazine.

Amination of the hydroxide ion to form hydroxylamine is only fast enough in very basic solutions (here chloramine

has already partly decomposed to hypochlorite and ammonia according to (372)):

Hydroxylamine cannot be isolated because it is rapidly aminated by chloramine to form the unstable hydroxylhydrazine  $H_2NNHOH$ , which eliminates water and forms diimine, whose decomposition has been described above (375). The net equation of the amination of hydroxide ions is therefore (361).

Analogous to the amination of  $NH_3$ ,  $NH_2Cl$ ,  $N_2H_4$ , sulfanes  $R_2S$  are aminated to  $[R_2S-NH_2]^+Cl^-$ , phosphanes  $R_3P$  are aminated to  $[R_3P-NH_2]^+Cl^-$ , arsanes  $R_3As$  are aminated to  $[R_3As-NH_2]^+Cl^-$ , and the cyanide ion  $CN^-$  is aminated to form cyanamide  $NC-NH_2$ .

Nucleophiles  $Nu^-$  attack the N-Cl bond ((371) and (378)), formally an electrophilic or nucleophilic substitution of chlorine. In the reaction of electrophiles  $E^+$  with chloramine  $NH_2Cl$ , a nitrogen bound proton is substituted. This results in the transfer of the  $NHCl^-$  to  $E^+$ .

Examples for this reaction are the chloramidation of chlorine in hypochloric acid

or of chloramine (372).

In radicalic reactions,  $NH_2Cl$  can react as a chlorinating agent:

Saturated hydrocarbons react similarly:

These reactions are believed to have a free radical mechanism where the neutral amino radical abstracts a hydrogen atom from the hydrocarbon.

The oxidative power of chloramine has been used for the oxidative coupling of X-H bonds ( $X$  = nonmetal).

Chloramine is used as a disinfectant for water because it is less aggressive than  $\text{Cl}_2$  and more stable against light than  $\text{ClO}^-$ .

### 8.2.2 Dichloramine

Dichloramine is highly unstable and has not been isolated as a pure substance yet. Its yellow aqueous solutions are almost undissociated ( $\text{p}K_a = 7$ ) and unprotonated.<sup>135</sup>

It is less polar than chloramine and has a higher solubility in unpolar solvents. Solutions containing  $\text{NH}_4^+$  are relatively stable at  $\text{pH} = 3.5\text{--}4$  with about 10% decomposition per day, whereas solutions without  $\text{NH}_4^+$  ions decompose totally within hours. The ammonium ions inhibit the decomposition by reacting with hypochlorous acid  $\text{HOCl}$ , which is formed in small amounts by the hydrolysis of  $\text{NHCl}_2$  and accelerates the decomposition of dichloramine.

The decomposition of dichloramine without  $\text{NH}_4^+$  ions is dependant on the pH of the solution. In very acidic solution ( $\text{pH} < 4$ ), dichloramine disproportionates to trichloramine:

In mildly acidic solution ( $\text{pH} = 4$ ), dinitrogen and trichloramine are formed.

At pH 12, hypochlorite is formed:

In the pH range of 4 to 12, both reactions (400) and (401) take place, for example, at  $\text{pH} = 7$  the ratio of (400) and (401) is 1:10.

Dichloramine is an intermediate in the chlorination of  $\text{NH}_3$  in acidic solution that leads to  $\text{NCl}_3$  (see Section 8.2.3), but the best synthesis is the chlorination of ammonium ions with hypochlorous acid (ratio  $\text{NH}_4^+:\text{HOCl} = 1:2$ ) in dilute aqueous solution at pH values around 4.  $\text{NH}_2\text{Cl}$  is an intermediate in this reaction since the chlorination of  $\text{NH}_2\text{Cl}$  is slower than the chlorination of  $\text{NH}_3$ .

Dichloramine can be extracted with organic solvents. Comproportionation of  $\text{NH}_2\text{Cl}$  and  $\text{NCl}_3$  in organic solvents at 195 K also gives dichloramine:

As explained above, dichloramine is formed during the disproportionation of chloramine at  $\text{pH} 3.5\text{--}4$ , thus it can be obtained by adding perchloric acid to a solution of chloramine:

Pure, ammonia-free solutions of dichloramine can be obtained by passing chloramine through an acidic ion-exchange column (which exchanges  $\text{NH}_4^+$  ions from the disproportionation reaction (403) against  $\text{H}^+$ ).

In analogy to chloramines, dichloramine can react as a chlorinating agent and can transfer positive chlorine to ammonia or water.

The equilibrium of hydrolysis is on the side of  $\text{HNCl}_2$ . Hypochlorous acid, which is formed during the hydrolysis of  $\text{HNCl}_2$ , chlorinates  $\text{HNCl}_2$  to  $\text{NCl}_3$ .

This reaction is much faster than the hydrolysis and lowers the  $\text{HOCl}$  concentration so that the hydrolysis equilibrium is shifted to the  $\text{HOCl}$  side. Excess  $\text{HNCl}_2$  then reacts with the formed trichloramine to form decomposition products.

The formed hypochlorous acid further accelerates the decomposition. The reaction rate of (407) increases rapidly with increasing pH so that the decomposition of  $\text{NCl}_3$  according to (407) is faster than the formation of  $\text{NCl}_3$ , thus producing only a small static concentration and a small yield of  $\text{NCl}_3$ . In acidic solution, the decomposition of  $\text{NCl}_3$  is slower,  $\text{NCl}_3$  is formed in good yield.

### 8.2.3 Nitrogen Trichloride

Nitrogen trichloride is a dark yellow liquid ( $\rho = 1.65 \text{ g cm}^{-3}$ ) that is only poorly soluble in water but dissolves well in nonpolar solvents like  $\text{CCl}_4$  or  $\text{CS}_2$ . For the same reasons as for  $\text{NF}_3$ ,  $\text{NCl}_3$  has a low polarity ( $\mu = 0.6(2) \text{ D}$ ).  $\text{NCl}_3$  is a highly endothermic compound ( $\Delta H_f = 229 \text{ kJ mol}^{-1}$ ) that explodes when heated to 363 K, after slight mechanical stress or by contact with oxidizable organic matter. The low solubility in water can cause the formation of droplets of  $\text{NCl}_3$  in the aqueous solution that readily explode. The explosive decomposition produces dinitrogen and  $\text{Cl}_2$  via a radical decomposition mechanism.

Nitrogen trichloride is more stable than chloramine and dichloramine. Decomposition occurs only slowly at room temperature. The decomposition is accelerated by light, arsenic trifluoride, or silver halides.

Nitrogen trichloride is formed in the reaction of chlorine with solutions of ammonium chloride in water at pH 3–4.<sup>135</sup>

Nitrogen trichloride is also produced by electrolysis of  $\text{NH}_4\text{Cl}$  solutions. The reaction is carried out in a buffer system because of the formed  $\text{HCl}$ .  $\text{NCl}_3$  can be extracted with organic solvents like carbon tetrachloride. Ammonium ions can be chlorinated with hypochlorous acid at pH 3–4:

In this reaction,  $\text{NH}_2\text{Cl}$  and  $\text{NHCl}_2$  are intermediates, the chlorination speed decreases from  $\text{NH}_4^+$  over  $\text{NH}_2\text{Cl}$  to  $\text{NHCl}_2$ . Quantitative yields are not achieved because the  $\text{NCl}_3$  formed can be attacked by  $\text{NHCl}_2$  according to (407).

$\text{NCl}_3$  has a low basicity and decomposes on reaction with very strong acids  $\text{HX}$ , forming  $\text{NH}_4\text{X}$  and  $\text{Cl}_2$ .  $\text{HCl}$  reacts with  $\text{NCl}_3$  to form ammonium chloride and chlorine:

Salts of  $\text{HNCl}_3^+$  have not been isolated, but  $\text{HNCl}_3^+$  has been observed mass spectrometrically. Addition of the Lewis acid  $\text{Cl}^+$  to  $\text{NCl}_3$  in  $\text{SO}_2$  yields colorless  $\text{NCl}_4^+$  ions ( $T_d$  symmetry):

Oxygen can also react with  $\text{NCl}_3$ , but  $\text{ONCl}_3$  is only known in the form of the light yellow, planar cation  $\text{NOCl}_2^+$  ( $d(\text{N}-\text{Cl})$  161 and 172 pm,  $d(\text{N}-\text{O})$  130 pm,  $\angle(\text{ONCl})$  118.5/117.9°,  $\angle(\text{ClNCl})$  118.5°).<sup>136</sup>

A quaternary  $\text{ONCl}(\text{F})^+$  cation was formed in the reaction of  $\text{NOCl}$  with  $\text{NF}_2^+$ .

$\text{ONClF}^+$  decomposes in  $\text{SO}_2$  solution at 195 K in the course of several days to form  $\text{NO}^+$  and  $\text{ClF}$ . The stability of the  $\text{NOX}_2^+$  salts decreases in the order  $\text{NOF}_2^+ > \text{NOCl}_2^+ \sim \text{NOCl}(\text{F})^+$ .

The reactions of  $\text{NCl}_3$  with water and ammonia proceed as follows:

In these reactions,  $\text{NCl}_3$  acts as a chlorinating agent by transferring positively charged chlorine  $\text{Cl}^+$ . During the slow hydrolysis of  $\text{NCl}_3$ ,  $\text{NHCl}_2$  and hypochlorous acid are initially formed:

The equilibrium is on the left side, but the  $\text{NHCl}_2$  formed decomposes by the reaction with  $\text{NCl}_3$  according to (407) to yield the overall equation (415).

The first step in the reaction of  $\text{HNCl}_2$  and  $\text{NCl}_3$  is the formation of tetrachlorohydrazine from the reaction of  $\text{NCl}_3$  with the nucleophile  $\text{NCl}_2^-$ , which is formed from  $\text{HNCl}_2$ . Here  $\text{NCl}_3$  is an electrophilic amination agent that transfers  $\text{NCl}_2^+$ .

The tetrachlorohydrazine formed is not stable, and instantly decomposes via the unstable dichlorodiazene  $\text{N}_2\text{Cl}_2$  to dinitrogen.

The reaction of  $\text{NCl}_3$  with bromide anions in aqueous solution proceeds via an  $\text{NBrCl}_2$  intermediate to form dinitrogen and  $\text{Br}_2$ .<sup>137</sup>

### 8.3 Nitrogen Bromides

Aqueous solutions of bromamine  $\text{NH}_2\text{Br}$  are formed during the bromination of  $\text{NH}_3$  with hypobromite:<sup>4</sup>

Ethereal solutions can be obtained by passing ammonia through an ethereal solution of  $\text{Br}_2$ .

After the removal of insoluble  $\text{NH}_4\text{Br}$ , the ethereal solution is poured into pentane at 153 K, and black–violet  $\text{NH}_2\text{Br}$  precipitates.

$\text{NH}_2\text{Br}$  is a weak base ( $\text{p}K_b = 7.7$ ). In absence of ammonia,  $\text{NH}_2\text{Br}$  reacts in an equilibrium in aqueous and ethereal solutions to form dibromamine  $\text{NHBr}_2$ .

The equilibrium can be shifted to the right side by removing ammonia with  $\text{CaCl}_2$  or acid. Solutions of  $\text{NHBr}_2$  in ether are short-lived.

$\text{NH}_2\text{Br}$  decomposes in the presence of ammonia more or less rapidly like chloramine ( $t_{1/2} = 580$  min at 203 K,  $t_{1/2} = 124$  min at 273 K,  $t_{1/2} = 6.9$  min at 297 K).

In this reaction hydrazine is an intermediate, but contrary to chloramine, hydrazine reacts rapidly with  $\text{NH}_2\text{Br}$ , so that hydrazine can not be isolated as in the  $\text{NH}_2\text{Cl}/\text{NH}_3$  system.

The equilibria between the various bromination products of ammonia are strongly influenced by the pH value. At pH values above 9, the equilibria are displaced almost totally toward  $\text{BrNH}_2$ . With high  $\text{NH}_3:\text{Br}_2$  ratios and pH values between 6.3 and 5.8, the very unstable  $\text{NHBBr}_2$  is the main species. At low  $\text{NH}_3:\text{Br}_2$  ratios and pH values lower than 6,  $\text{NBr}_3$  is the dominant product.  $\text{NBr}_3$  can be extracted with various solvents such as chloroform, carbon tetrachloride, or ether. Pure  $\text{NBr}_3$  is available by treating  $(\text{Me}_3\text{Si})_2\text{NBr}$  with  $\text{BrCl}$  in pentane at 286 K.  $\text{NBr}_3$  is a deep red, insoluble substance in pentane that explodes easily even at 173 K.<sup>138</sup>

## 8.4 Nitrogen Iodides

Addition of  $\text{I}_2$  to liquid ammonia at temperatures below 240 K results in the precipitation of green  $\text{NI}_3 \cdot 3\text{NH}_3$ . The reaction proceeds via ammonia-iodine charge transfer complexes ( $\text{I}_2 \cdot \text{NH}_3$  and  $\text{I}_2 \cdot 2\text{NH}_3$  are known), to iodamine, diiodamine, and to triiodamine. At temperatures below 200 K, red  $\text{NI}_3 \cdot 5\text{NH}_3$  is obtained.<sup>4</sup>

At temperatures above 40 K,  $\text{NI}_3 \cdot 3\text{NH}_3$  loses ammonia to form the red–brown to black  $\text{NI}_3 \cdot \text{NH}_3$ . The ammonia adduct  $\text{NI}_3 \cdot \text{NH}_3$  precipitates when ammonia is passed through an aqueous solution of potassium triiodide. In an atmosphere with a high partial pressure of ammonia, it can be stored in the dark for a long time. The dry compound is extremely sensitive and explodes after the slightest mechanical stress, slight heating, or irradiation.

The equilibria (426) are reversible, and on the side of the ammonia-iodine charge transfer complex. Solvation of  $\text{NI}_3 \cdot \text{NH}_3$  in diethylether in the presence of ammonium iodide yields the ether-soluble charge transfer complex  $\text{NH}_3 \cdot \text{I}_2$ .

Removal of ammonia from  $\text{NI}_3 \cdot \text{NH}_3$  in vacuo results in the decomposition to dinitrogen and iodine.

In  $\text{NI}_3 \cdot \text{NH}_3$ , slightly distorted  $\text{NI}_4$  tetrahedra are linked by shared corners into indefinite  $\text{I}-\text{N}-\text{I}-\text{N}-\text{I}$  chains ( $d(\text{N}-\text{I}_{\text{bridge}})$  230 pm,  $d(\text{N}-\text{I}_{\text{term}})$  214 pm). Ammonia forms a charge transfer complex with the terminal iodine atoms ( $d(\text{N}-\text{I} \cdots \text{NH}_3)$  253 pm).

When a saturated solution of  $\text{NI}_3 \cdot 3\text{NH}_3$  in liquid ammonia in the presence of  $\text{NH}_4\text{I}$  is cooled to below 198 K, a red adduct  $\text{NH}_2\text{I} \cdot \text{NH}_3$  (see (426)) precipitates. Storing this adduct at 183 K in vacuo results in the removal of ammonia to form the black iodamine  $\text{NH}_2\text{I}$ . Warming up  $\text{NH}_2\text{I}$  to 213 K in vacuo removes another ammonia molecule and yields the very unstable diiodamine  $\text{NHI}_2$ .

Pure nitrogen triiodide ( $\Delta H_f = +290 \text{ kJ mol}^{-1}$ )<sup>139</sup> can be obtained by the reaction of iodine fluoride with boron nitride at 263 K in  $\text{CF}_3\text{Cl}$ .

The deep red substance can be purified by sublimation at 253 K under partial decomposition. It decomposes fast and often explosively. This makes  $\text{NI}_3$  thermally more stable than  $\text{NBr}_3$  but less stable than  $\text{NCl}_3$ .

## 8.5 Mixed Nitrogen Halides

### 8.5.1 Dichlorofluoramine

Dichlorofluoramine has a boiling point of 270 K and is explosive in the liquid as well as in the solid state.  $\text{FNCl}_2$  can be prepared by passing a  $\text{ClF}/\text{N}_2$  mixture over sodium azide:

The low-temperature chlorination of  $\text{FC(O)NF}_2$  is also a convenient method for the synthesis of  $\text{Cl}_2\text{NF}$ .<sup>140</sup> Alternatively,  $\text{FNCl}_2$  can be obtained from  $\text{ClF}$  and  $\text{ClN}_3$  in perfluorinated ether. Irradiation of  $\text{FNCl}_2$  with a high-pressure Hg lamp leads to the formation of *cis*- $\text{N}_2\text{F}_2$ .

### 8.5.2 Chlorodifluoramine

Chlorodifluoramine ( $\Delta H_f \geq -104 \text{ kJ mol}^{-1}$ ) boils at 207.1 K, and has a melting point below 78 K. In Pyrex glass, it is thermally stable up to 393 K, where it decomposes to  $\text{NF}_3$ ,  $\text{N}_2$ , and  $\text{Cl}_2$ . Irradiation at wavelengths  $< 300 \text{ nm}$  results in the reversible photochemical decomposition to  $\text{N}_2\text{F}_4$  and  $\text{Cl}_2$ .<sup>141</sup>

As a Lewis base, chlorodifluoramine is intermediate in strength between  $\text{HNF}_2$  and  $\text{NF}_3$ . It reacts vigorously with  $\text{NO}$  even at low temperatures:

Chlorodifluoramine is accessible by chlorinating  $\text{HNF}_2$  with gaseous  $\text{Cl}_2$  in  $\text{CCl}_4$  solutions or with aqueous  $\text{NaOCl}$  at 273 K and pH 6–6.5. At pH 12, the major product is  $\text{N}_2\text{F}_4$ , whereas between pH 6–12 both  $\text{ClNF}_2$  and  $\text{N}_2\text{F}_4$  result. Difluoramine also reacts with  $\text{HOCl}$ ,  $t\text{BuOCl}$ ,  $\text{SOCl}_2$ ,  $\text{COCl}_2$ ,  $\text{HCl}$ ,  $\text{ClF}_3$ , and  $\text{ClF}$  to form  $\text{ClNF}_2$ .

Tetrafluorohydrazine is converted to  $\text{ClNF}_2$  by chlorine under UV irradiation. Reaction of fluorine with chlorine azide also yields chlorodifluoramine.

### 8.5.3 Bromodifluoramine

Bromodifluoramine ( $\Delta H_f^\circ = -39 \text{ kJ mol}^{-1}$ ) is a colorless liquid with a boiling point of 237 K and decomposes rapidly on warming.<sup>142</sup> Bromodifluoramine is prepared by the reaction of aqueous bromine with  $\text{HNF}_2$  in the presence of  $\text{HgO}$ .

It was also prepared from  $\text{NF}_2\cdot$  and bromine radicals, which were generated by microwave discharge in an atmosphere of  $\text{N}_2\text{F}_4$  and  $\text{Br}_2$ :

### 8.5.4 Dibromiodamine

The reaction of tribromamine with iodine in dichloromethane yields red-brown  $\text{NBr}_2\text{I}$ , which is stable up to 253 K.<sup>138</sup>

## 8.6 Halogen Azides

In the gas phase, the halogen azides have a *trans* *Cs*-configuration like  $\text{HN}_3$  with an  $\text{N-N-N}$  bond angle around  $171^\circ$ .<sup>127,143</sup> The  $\text{N-N}$  bond lengths are significantly different.

**Figure 15** Negative hyperconjugation ion halogen azides  $\text{XN}_3$

The  $\text{N}_\alpha\text{-N}_\beta$  bond length is around 124 pm and  $\text{N}_\beta\text{-N}_\gamma$  is around 113 pm. The  $\text{N}_\alpha\text{-N}_\beta$  bond can be considered as a long double bond, and the  $\text{N}_\beta\text{-N}_\gamma$  bond is a weak triple bond. The azides show a strong delocalization of the  $\pi$ -electron density over the complete molecule. A donor-accepter interaction leads to electron donation from a filled bonding  $\sigma(\text{X-N}_\alpha)$  orbital to an empty antibonding  $\pi^*(\text{N}_\beta\text{-N}_\gamma)$  orbital (see Figure 15).<sup>144</sup> The consequences of this negative hyperconjugation are the long and weak  $\text{X-N}_\alpha$  bond, the short and strong  $\text{N}_\alpha\text{-N}_\beta$  bond, the weak  $\text{N}_\beta\text{-N}_\gamma$  triple bond and the angle at the central  $\text{N}_2$  nitrogen atom.<sup>145</sup>

The crystal structure of iodine azide is polymeric with longer  $\text{N-I}$  distances than in the gas phase, because the  $\text{IN}_3$  units are connected by linear coordinated iodine atoms.<sup>146</sup> Structural data of the halogen azides are summarized in Table 38.

The halogen azides are prepared by the reaction of metal azides with halogens or the hypohalogenic acids.

All halogen azides are sensitive and explode easily. The sensitivity decreases in the order  $\text{FN}_3 > \text{ClN}_3 > \text{BrN}_3 > \text{IN}_3$ . Fluorine azide decomposes to form dinitrogen difluoride and dinitrogen.

The thermal decomposition of the other halogen azides is not initiated by the breaking of the  $\text{X-N}_3$  bond, but, at least in

**Table 38** Structural data of halogen azides compared to  $\text{HN}_3$

|                                                         | $\text{HN}_3$ (g) | $\text{FN}_3$ (g) | $\text{ClN}_3$ (g) | $\text{BrN}_3$ (g) | $\text{IN}_3$ (g) | $\text{IN}_3$ (s) |

the gas phase, by dissociation into  $\text{XN}(\text{X}^3\Sigma^-)$  and  $\text{N}_2(\text{X}^1\Sigma_g^+)$ .<sup>147</sup>

Even though this decomposition is spin forbidden, pyrolysis experiments have clearly shown the fragmentation into  $\text{XN}(\text{X}^3\Sigma^-)$  fragments and  $\text{N}_2$ . The end products of the decomposition of chlorine, bromine, and iodine azide are dinitrogen and the dihalides. Iodine also forms other azide species, the orange  $\text{I}(\text{N}_3)_2^-$ , the deep violet  $\text{I}_2\text{N}_3^-$ ,<sup>148</sup> the deep carmine-red  $\text{I}_2\text{N}_3^+$ ,<sup>149</sup> and the yellow  $\text{I}(\text{N}_3)_2^+$ .<sup>150</sup>

Chlorine, bromine, and iodine azide can act as donors of positive halides. The reaction of chlorine azide with water yields hydrazoic acid and hypochloric acid:

The halogen azides  $\text{XN}_3$  ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) react with element chlorides (e.g.  $\text{BX}_3$ ,  $\text{AlX}_3$ ,  $\text{SnCl}_4$ ,  $\text{SbCl}_5$ ,  $\text{TiCl}_4$ ,  $\text{NbCl}_5$ ,  $\text{TaCl}_5$ ,  $\text{CrCl}_3$ ,  $\text{WCl}_6$ ,  $\text{ReCl}_5$ ,  $\text{UCl}_6$ ) under halogen elimination to form the element halogenide azides.<sup>151</sup>

With other element halides ( $\text{SnCl}_2$ ,  $\text{PCl}_3$ , and  $\text{SbBr}_3$ ) oxidative addition occurs:

## 9 OXOHALIDES OF NITROGEN

### 9.1 Nitrosyl Halides

The nitrosyl halides all assume an angular structure. In the gas phase, the nitrogen–halogen bond distances are quite long (see Table 39) compared to  $\text{NF}_3$  (136.5(2) pm) and  $\text{NCl}_3$  (175.9(2) pm) and the nitrogen–oxygen bond distances are so short that they are in the range of triple bonds.

**Table 39** Physical properties and bonding parameters of nitrosyl halides

|                                                  | FNO                             | ClNO                            | BrNO       |

The bond polarity has a strong influence on the N–X bond length, for less basic groups  $\text{X}^-$  a complete shift to  $\text{NO}^+\text{X}^-$  is observed (e.g.  $\text{NO}^+\text{PF}_6^-$ ,  $\text{NO}^+\text{ClO}_4^-$ ). In the solid state, both NOF and NOCl show longer N–X bonds and shorter N–O bonds. The effect is more pronounced for chlorine and is explained in terms of a stronger ionic character in the solid state.<sup>152</sup> IR data indicate a similar behavior of NOBr.<sup>153</sup> For a detailed analysis of the bonding situation, see Ref. 154.

Nitrosyl halides can be obtained by the direct reaction of the respective halides with nitrogen monoxide at slightly elevated temperatures (310–320 K).

In the case of fluorine, NOF<sub>3</sub> is also produced during this reaction. The stability of the nitrosyl halides decreases in the order  $\text{F} > \text{Cl} > \text{Br}$ . NOCl is 0.5% decomposed at 298 K, NOBr is 7% decomposed, and nitrosyl iodide is unstable and decomposes rapidly to nitrogen monoxide and iodine, and has so far only been observed in matrix isolation at 9 K.

NOCl decomposes at 373 K to form NO and chlorine. NOCl is present in aqua regia and is responsible for its red–yellow color. In the presence of traces of water, NOCl is very aggressive and can only be stored in Tantalum or glass vessels. Dry NOCl does not attack nickel, lead, platinum, and some polymers.

NOCl is the mixed anhydride of nitrous acid and hydrochloric acid and is easily hydrolyzed by water.

Therefore, water has to be excluded during the synthesis, for example, by passing HCl gas into liquid  $\text{N}_2\text{O}_3$  in the presence of  $\text{P}_2\text{O}_5$  as a dehydrating agent.

In another synthesis, sodium chloride reacts with nitrosyl hydrogensulfate to form NOCl:

A laboratory synthesis uses sodium nitrite and hydrochloric acid:

Other preparations include the treatment of  $\text{KNO}_2\text{--AlCl}_3$  melts with ammonium chloride, reaction of nitric acid with HCl in aqua regia, or the reactions of metal chlorides with nitric acid.

NOF, NOCl, and NOBr form  $\text{NO}^+$  salts in reactions with halogen acceptors:

NOBr has been obtained from nitrogen dioxide and potassium bromide:

In the system,  $\text{NO}/\text{Br}_2$   $\text{NOBr}_3$  is the main compound found below 293 K, above 313 K NOBr is the main compound.<sup>155</sup>

The photosensitive isonitrosylhalides NOX (X = Cl, Br) can be obtained using matrix-isolation technique by irradiation of the nitrosyl halides.<sup>156</sup>

## 9.2 Nitryl Halides

The nitryl halides ( $C_{2v}$  symmetry) are planar in analogy to the isoelectronic  $\text{CO}_3^{2-}$ . The gas phase and solid-state structures for  $\text{ClNO}_2$  both show covalently bound molecules (see Table 40).<sup>154</sup> In contrast to the nitrosyl halides, the halogen–nitrogen bond distances in the gas phase and in the solid state are similar.<sup>152</sup> The nitryl halides  $\text{NO}_2\text{F}$  and  $\text{NO}_2\text{Cl}$  are the mixed anhydrides of nitric acid and hydrofluoric or hydrochloric acid, respectively.

**Table 40** Properties and bonding parameters of nitryl halides

|                                                  | $\text{FNO}_2$ | $\text{ClNO}_2$                                                  |

| $\mu$ [D]                                        | 0.47           | 0.42                                                             |

Similar to the nitrosyl halides, the nitryl halides are easily hydrolyzed. During the synthesis, water has to be excluded, either by removing it:

or by using a synthetic route that does not produce water:

The oxidation of nitrosyl chloride with ozone,  $\text{N}_2\text{O}_5$ ,  $\text{Cl}_2\text{O}$ , and  $\text{ClO}_2$  also yields nitryl chloride.

Nitrosyl fluoride was also made from  $\text{NO}_2$  and  $\text{CoF}_3$  and by the reaction of nitryl chloride with hydrogen fluoride:

The stability of the nitryl halides follows the stability of the nitrosyl halides,  $\text{F} > \text{Cl} > \text{Br} > \text{I}$ . Nitryl bromide  $\text{BrNO}_2$  exists in equilibrium with  $\text{NO}_2/\text{N}_2\text{O}_4$  at room temperature and can be studied spectroscopically.<sup>157</sup>  $\text{INO}_2$  has a lifetime of only a few seconds at room temperature.

Reaction of the nitryl halides with strong Lewis acids yields nitryl salts with the linear  $\text{NO}_2^+$  cation (**92**) ( $d(\text{N}=\text{O})$  115.4 pm) (see Figure 16).

**Figure 16** Lewis structure of the  $\text{NO}_2^+$  cation

At low temperatures, the structural isomers, the halogen nitrites (nitrosyl hypohalides)  $\text{XONO}$  can be observed in the photolysis reaction of  $\text{X}_2/\text{NO}_2$  mixtures.

Nitryl chloride reacts with zinc, mercury, and bismuth to form mixtures of the metal chlorides and nitrates, but does not react with copper, magnesium, iron, aluminum, or tin at 243 K. In the reaction with ammonia, nitryl chloride acts as a source of positive chlorine:

### 9.3 Trifluoramine Oxide

Trifluoramine oxide (**93**) (Figure 17) is a colorless and highly toxic gas ( $\Delta H_f = -71 \text{ kJ mol}^{-1}$ ) with a melting point of 113 K and a boiling point of 185.6 K. It has a tetrahedral structure ( $C_{3v}$  symmetry) and is isoelectronic to  $\text{NF}_4^+$ .<sup>154</sup> The NF bond length (143 pm) is significantly longer than in  $\text{NF}_4^+$  (130 pm), the NO bond length (116 pm) is shorter than the NO bond length in HNO (121 pm), thus indicating a bond order of around 2.

The bonding situation can be explained by negative hyperconjugation. Electron density is transferred from the oxygen p lone pairs to one of the antibonding  $\sigma^*$  (N–F) orbitals, thus strengthening the NO bond and weakening the NF bonds. The reaction of  $\text{NF}_3$  and  $\text{O}_2$  in electric discharge results in formation of  $\text{NOF}_3$ .

$\text{ONF}_3$  is also accessible from the reaction of nitrosyl fluoride with iridium hexafluoride:

**Figure 17** Lewis structure of  $\text{F}_3\text{NO}$ 

Other methods for the preparation of  $\text{ONF}_3$  include the fluorination of NO and the reaction of  $\text{NF}_3$  with  $\text{N}_2\text{O}$ .<sup>158</sup>

Irradiation with ultraviolet light forms the  $\text{NOF}_2\cdot$  radical.  $\text{NOF}_3$  decomposes at temperatures above 600 K to yield NOF, NO,  $\text{NO}_2$ , and  $\text{NO}_2\text{F}$ . It is a strong oxidizing agent toward organic and inorganic compounds.

As for  $\text{NF}_3$ , reactions with  $\text{NOF}_3$  require an activation energy and do not occur spontaneously at room temperature, even though they are thermodynamically favored. In many instances, reactions result in fluorination rather than oxygenation, in keeping with the greater strength of the N–O bond.

On reaction with strong fluorine acceptors ( $\text{BF}_3$ ,  $\text{AsF}_5$ ,  $\text{SbF}_5$ ),  $\text{NOF}_3$  can lose fluoride and form the planar  $\text{ONF}_2^+$  cation ( $d(\text{N–F})$  128.4 pm,  $d(\text{N–O})$  111.4 pm,  $\angle(\text{F–N–F})$  107.9°,  $\angle(\text{F–N–O})$  126.0°).<sup>159</sup>

The  $\text{NOF}_2^+$  cation reacts with  $\text{HN}_3$  to form the  $\text{N}_3\text{NOF}^+$  cation:

### 9.4 Nitrosodifluoramine

The reaction of the normally relatively unreactive  $\text{N}_2\text{O}$  with difluorine gas at 77 K under UV irradiation yields a dark blue liquid, nitrosodifluoramine  $\text{F}_2\text{NNO}$  (**94**) (Figure 18).<sup>160</sup>

Nitrosodifluoramine (**94**) can also be obtained by reacting tetrafluorohydrazine with a tenfold excess of NO at 583 K followed by quenching at 77 K.

**Figure 18** Lewis structure of  $\text{F}_2\text{NNO}$

**Table 41** Properties and bonding parameters of halogen nitrates

Nitrosodifluoramine (**94**) decomposes at 133 K to form tetrafluorohydrazine and NO, the reverse of the formation reaction (481).

## 9.5 Halogen Nitrates

The halogen nitrates have planar  $C_s$  structures (see Table 41). The dissociation to XO and NO<sub>2</sub> gets easier from fluorine to iodine.

In the gas phase, the N–O bonds of chlorine and bromine nitrate are shorter and the O–X bonds longer than in the crystal structure.<sup>154,161</sup> In the solid state of the halogen nitrates, as for the nitrosyl halides, the contribution of the ionic  $\text{X}^+ \text{NO}_3^-$  structure is higher.<sup>152</sup> This makes the N–O bond shorter and the O–X bond longer. The crystal structures can be considered as adducts of the halogen oxide XO• and the NO<sub>2</sub>• radicals.

Fluorine nitrate is best prepared by the fluorination of nitric acid:

The chlorine compound can be synthesized from nitric acid and ClF:

or by reacting N<sub>2</sub>O<sub>5</sub> with Cl<sub>2</sub>O at 253 K:

The chlorine, bromine, and iodine nitrates (X = Cl, Br, I) can also be prepared by the reaction of silver nitrate with the halides.

Bromine nitrate reacts with N<sub>2</sub>O<sub>5</sub> to form an adduct.

Bromine nitrate disproportionates to bromine, oxygen, and N<sub>2</sub>O<sub>5</sub> at 273 K:<sup>162</sup>

The unstable chloryl nitrate was detected in the reaction of ClO<sub>2</sub> with NO<sub>3</sub>.<sup>163</sup>

and bromyl nitrate from the ozonization of bromine nitrate at 196 K:

Bromyl nitrate thermally decomposes to dibromine, dioxygen, and nitrogen dioxide.

The high levels of chlorine radicals ClO<sub>x</sub> observed in the polar stratosphere couple with nitrogen oxides NO<sub>x</sub>, resulting in the removal of reactive chlorine species by conversion into

temporary reservoir species. The association reaction between ClO and NO<sub>2</sub> forming chlorine nitrate has been considered the most significant:

Chlorine nitrate and HCl are considered to be the most important chlorine reservoir species in the stratosphere.<sup>164</sup> Iodine nitrate has also been considered as a reservoir species for iodine radicals that could destroy tropospheric ozone, but photodissociation of IONO<sub>2</sub> to form iodine radicals is only effective at temperatures below 290 K, at higher temperatures thermal decomposition takes place which does not yield iodine radicals.<sup>165</sup>

Several iodine nitrates in the oxidation state +III are known: I(ONO<sub>2</sub>)<sub>3</sub> and CF<sub>3</sub>I(ONO<sub>2</sub>)<sub>2</sub>.<sup>166</sup> The other halogens do not form binary nitrates in the oxidation state +III. Iodine (III) nitrates are available by substitution of iodine(III) compounds

or by the oxidation of iodine(I) compounds:

I(ONO<sub>2</sub>)<sub>3</sub> has also been prepared by the oxidation of iodine with ClONO<sub>2</sub> at 238 K:

Vibrational spectra indicate a polymeric structure with bridging nitrate ligands for I(ONO<sub>2</sub>)<sub>3</sub>. The fluffy light yellow solid decomposes at 273 K to form N<sub>2</sub>O<sub>5</sub> and IONO<sub>2</sub>, which is only marginally stable and decomposes under formation of N<sub>2</sub>O<sub>5</sub>.

The XeNO<sub>3</sub><sup>+</sup> cation, which is isoelectronic to the halogen nitrates has been detected in a mass spectrometer and seems to have the same connectivity as the halogen nitrates, but can isomerize to an OXeNO<sub>2</sub> structure. XeNO<sub>2</sub><sup>+</sup> was also detected, here xenon acts as a ligand of the nitronium ion. In the solid state, NO<sub>2</sub><sup>+</sup>Xe<sub>2</sub>F<sub>13</sub><sup>−</sup> consists of X<sub>2</sub>F<sub>13</sub><sup>−</sup> and nitronium ions. In solution, the reaction of xenon difluoride with a HNO<sub>3</sub>/NO<sub>2</sub> mixture produces the neutral species Xe(ONO<sub>2</sub>)<sub>2</sub>.<sup>167</sup>

## 1 INTRODUCTION

Reduced nitrogen is essential to all forms of life for it is present in many important and universal biological molecules such as nucleotides and amino acids, the building blocks of DNA and proteins. Although abundant in its molecular state in today's earth atmosphere (78%), dinitrogen is very difficult to reduce. Indeed, the N≡N triple bond dissociation energy, as high as 940 kJ mol<sup>-1</sup>, and the unstability of some reduced intermediates make N<sub>2</sub> kinetically very stable. Thermodynamically, however, its reduction is generally favorable: for instance  $\Delta G^0$  for  $N_2 + 3H_2 \rightarrow 2NH_3$  is -32 kJ mol<sup>-1</sup> in the gas phase.<sup>1</sup> Hence, dinitrogen is often referred to as an inert medium, as inferred by the Greek root of its name in French: *azote* (without life). Nevertheless, a restricted class of microorganisms called diazotrophs, comprising different archaea and bacteria, are able to overcome this relative inertness thanks to the nitrogenase enzyme, which catalyzes the biological reduction of dinitrogen to ammonia (see *Nitrogenase Catalysis & Assembly*). Ammonia, in the protonated form of ammonium, is indeed the primary entry point of fixed nitrogen into the living world, mainly via the glutamate/glutamine biosynthesis pathway of plants. Before the advent of an efficient artificial ammonia synthesis (the Haber–Bosch process) at the beginning of the twentieth century,<sup>2</sup> dinitrogen reduction by nitrogenases was even the major (and almost the sole) provider of primary assimilable nitrogen for living organisms.<sup>3</sup>

The most extensively studied nitrogenase enzyme contains two kinds of transition metals, that is, iron and molybdenum, and is called molybdenum nitrogenase.<sup>4–7</sup> In growth conditions where molybdenum concentration is low, a nitrogenase depending on iron and vanadium is expressed.<sup>8–11</sup>

When both molybdenum and vanadium are unavailable, a third type of nitrogenase is expressed that contains iron as the only transition metal.<sup>8,12,13</sup> The vanadium–nitrogenase and iron-only nitrogenases, also known as alternative nitrogenases, are related to the molybdenum nitrogenase but are all genetically distinct. A fourth and completely different ‘nonconventional’ type of nitrogenase is known; it also contains iron and molybdenum, but couples dinitrogen reduction to the oxidation of superoxide and carbon monoxide.<sup>14</sup>

Mo-nitrogenase is the only one for which both detailed structural and mechanistic data are available.<sup>4–7,15–17</sup> The enzymatic complex comprises two proteins: the iron-protein and the molybdenum iron-protein. The Fe-protein is an  $\alpha_2$  homodimer with a Fe<sub>4</sub>S<sub>4</sub> cluster (see *Iron–Sulfur Models of Protein Active Sites; Iron–Sulfur Proteins*) bridging the two  $\alpha$ -subunits via four iron-cysteinate ligations. Each  $\alpha$ -monomer of the iron-protein possesses a nucleotide-binding site (ATP or ADP). The Fe-protein is a specific reductant of the MoFe-protein, an event that depends on, and is coupled to, the hydrolysis of MgATP. The MoFe-protein is an  $\alpha_2\beta_2$  tetramer and contains two types of metal–sulfur centers: the so-called P-cluster of Fe<sub>8</sub>S<sub>7</sub> stoichiometry that is located at the interface of each homologous  $\alpha$ – $\beta$  subunit, and the FeMo-cofactor (MoFe<sub>7</sub>S<sub>9</sub>) found in each  $\alpha$ -subunit.

Two different structures are known for the P-cluster and are assigned to different cluster core oxidation states. In the reduced or P<sup>N</sup> (native) state, the Fe<sub>8</sub>S<sub>7</sub> cluster can be described as two Fe<sub>4</sub>S<sub>4</sub> cubes sharing one common hexacoordinate sulfur atom, the iron atoms being linked to the protein by cysteinate ligands, two of them bridging the subcubes. In the P<sup>OX</sup> state, oxidized by two electrons relative to P<sup>N</sup>, the central sulfur atom loses two bonds with two iron atoms in one of the subcubes, thus becoming more open. The tetrahedral coordination of these two iron atoms is then completed by extra ligations from neighboring cysteine or serine residues.

The FeMo-cofactor structure can be viewed as the assembly of two incomplete Fe<sub>4</sub>( $\mu_3$ -S)<sub>3</sub> and MoFe<sub>3</sub>( $\mu_3$ -S)<sub>3</sub> subcubes, linked together by three central  $\mu_2$ -S bridging sulfide ligands. The six central iron atoms form an approximate trigonal prism centered on a light atom ‘Y’ that has only been structurally recognized recently.<sup>17</sup> The identity of the light atom has been proposed to be nitrogen although carbon or oxygen have not been ruled out, while sulfur seems to be less likely. Theoretical investigations from different authors also concluded that ‘Y’ is most likely a nitrogen atom.<sup>18–20</sup> The pseudooctahedral coordination of molybdenum is completed by the exogenous bidentate (*R*)-homocitrate ligand and by imidazole from a neighboring histidine residue. A cysteine residue, covalently bound to the tetrahedral apical iron atom, provides the cofactor with its other protein ligation. The structure and location of the Mo-nitrogenase metal clusters are depicted in Figure 1.

The electrons transferred from the Fe<sub>4</sub>S<sub>4</sub> cluster of the iron-protein to the molybdenum–iron protein are believed to shuttle through the P-cluster before eventually reaching

**Figure 1** Schematic representation of the Fe-protein (60 kD,  $\alpha_2$  dimer) and the MoFe-protein (250 kD,  $\alpha_2\beta_2$  tetramer) of the Mo-nitrogenase. Outline of the electron transfer path through the metal clusters. Structure of the  $\text{Fe}_4\text{S}_4$  cluster of the Fe-protein. Structure of the P-cluster (in two oxidation states) and of the FeMo-cofactor in the MoFe-Protein. Limiting stoichiometry for the function of Mo-nitrogenase

the FeMo-co where  $N_2$  binding, reduction, and protonation occurs.

The limiting stoichiometry for the reduction of one equivalent of dinitrogen by Mo-nitrogenase to two equivalents of ammonia involves the hydrolysis of 16MgATP and the production of one molecule of dihydrogen, as outlined in Figure 1. The three metal clusters found in Mo-nitrogenase belong to the diverse class of iron–sulfur prosthetic centers largely distributed in all living organisms.<sup>21–24</sup> However, while the  $Fe_4S_4$  center is a common cluster found in many other iron–sulfur proteins, the P-cluster and the FeMo-cofactor represent to date unique structures in biology.

The complexity of the enzyme system, together with the extraordinary ambient conditions of transition metal-assisted dinitrogen reduction, have long fascinated inorganic chemists, still left with the high-temperature and high-pressure Haber–Bosch process for the artificial synthesis of ammonia from molecular nitrogen and hydrogen.

The current status of nitrogenase metal-cluster modeling by synthetic inorganic clusters and complexes is reported here. Modeling is to be understood not only in terms of structure and associated spectroscopic properties, but also in terms of function, that is, how well the models reproduce, or help to understand, the biological role of the metal–sulfur assemblies in nitrogenase, that is, electron transfer and the reduction of substrates.

The sequential electron transfer path in nitrogenase is followed: first models of the  $Fe_4S_4$  cluster of the iron-protein are discussed, then mimics of the P-cluster in the molybdenum–iron protein, and finally structural and functional models of the FeMo-cofactor are summarized.

## 2 MODELS FOR THE $Fe_4S_4$ CLUSTER OF NITROGENASE

$Fe_4S_4$  clusters with cysteinate ligation at iron, in their  $[Fe_4S_4]^{1+/2+/3+}$  redox states, are of pervasive occurrence in iron–sulfur proteins, functioning mostly as electron transfer relays as in ferredoxins ( $1+/2+$ ) and high-potential iron proteins ( $2+/3+$ ) (see *Iron–Sulfur Proteins*). Examples are also known where they are implied in catalysis.<sup>21,22</sup> In Mo-nitrogenase,<sup>4</sup> the Fe-protein specifically reduces the MoFe-protein with its  $Fe_4S_4$  cluster cycling between the  $[Fe_4S_4]^{1+}$  and  $[Fe_4S_4]^{2+}$  redox states at a potential of  $-0.31$  V versus the normal hydrogen electrode (NHE), that is lowered by about  $0.1$  V upon nucleotide binding. The  $Fe_4S_4$  cluster is symmetrically bridged between the  $\alpha$ -subunits of the iron-protein and is accessible to solvent molecules ( $H_2O$ ). Vicinal amino acid residues provide NH-S hydrogen bonds from amide groups to the iron–sulfur center. The  $[Fe_4S_4]^0$  state can be artificially generated as a stable center within the protein ( $-0.79$  V vs. NHE), however it is not known if this state is biologically relevant.<sup>25,26</sup>

The iron–sulfur cluster of the iron-protein in its  $[Fe_4S_4]^{1+}$  redox state exists in a mixture of spin states of similar energy in frozen solution ( $S = 3/2$ ) and ( $S = 1/2$ ). However, proton NMR analysis suggests that in standard conditions only one spin state is populated ( $S = 1/2$ ). Proton NMR spectroscopy is useful for the analysis of paramagnetic iron–sulfur clusters (those with the  $[Fe_4S_4]^{1+}$  and  $[Fe_4S_4]^{3+}$  core). Indeed, significant low- or high-field hyperfine isotropic shifts for the resonance of the protons bound at the carbon  $\beta$  to an iron center greatly simplify the analysis of the chemical environment of each iron center of the protein even if the signal is usually broad.  $^{57}Fe$  Mössbauer spectroscopy is a method of choice to assign the overall core oxidation state of a native or synthetic iron–sulfur cluster. There exists an empirical linear relationship between the  $^{57}Fe$  Mössbauer spectroscopy isomer shift (i.s.) and the oxidation state (or mean oxidation state) of an iron center (or a cluster of iron centers) in a pseudo-tetrahedral sulfur environment.<sup>27</sup>

Synthetic structural models for the  $Fe_4S_4$  clusters have been known for three decades now.<sup>27</sup> They are readily prepared by self-assembly from ferric or ferrous chloride, a source of reduced sulfur and thiolates, acting as ligands to the iron sites (Figure 2). Ligand-substitution reactions at the iron centers allow the tuning over a large window of their redox potential that is linearly linked to the electron donor/acceptor properties of the ligands, usually an alkyl or phenyl thiolate, or a halide (Figure 2). Crystal structures of model  $Fe_4S_4$  clusters with thiolate ligands are available for all  $[Fe_4S_4]^{1+/2+/3+}$  redox states, the  $[Fe_4S_4]^0$  state being only transiently generated in solution.

It has been shown that the  $Fe_4S_4$  cluster of the Fe-protein can be further reduced with nonbiological reductants from the  $[Fe_4S_4]^{1+}$  to the  $[Fe_4S_4]^0$  (all ferrous) redox state, which suggests that the Fe-protein could transfer two electrons per reduction cycle to the MoFe-protein.<sup>25</sup> Although there is no precedence for a functional  $[Fe_4S_4]^0$  state in biology, this is an attractive proposal considering that (1) substrates of nitrogenase can be reduced by multiple of two electrons, (2) the dicubane structure of both the P-cluster and the FeMo-cofactor is perhaps tailored to accept two electrons at once and (3) the homodimeric structure of the Fe-protein that may bind two donor molecules at a time.<sup>26,28</sup> Moreover, the redox potential originally reported for the  $[Fe_4S_4]^{1+/0}$  redox couple ( $-0.46$  V vs. NHE) was well within physiological range and only  $150$  mV negative of that of the  $[Fe_4S_4]^{2+/1+}$  redox couple. The biological relevance of the  $[Fe_4S_4]^0$  oxidation state however is contentious. In synthetic models with thiolate ligands, the all-ferrous redox state ( $[Fe_4S_4]^0$ ) is only detected transiently in some instances at the cyclic voltammetry timescale, and has only been generated, but not isolated, as a persistent species in solution in the case of  $Fe_4S_4(PR_3)_4$  bearing less relevant phosphine ligands, known to stabilize reduced oxidation states of metal complexes. Such a narrow potential separation ( $\Delta E = 0.15$  V) between the  $2+/1+$  and

**Figure 2** Electron transfer series in native and synthetic model clusters of the  $\text{Fe}_4\text{S}_4$  center in the Fe-protein. Redox potential versus NHE,  $^{57}\text{Fe}$  Mössbauer isomer shift ( $\delta$  at 4.2 K vs. iron), mean iron oxidation state, and spin state are indicated for each redox state. Syntheses and ligand-substitution reactions are indicated for synthetic clusters

$1+/0$  redox couples of the iron-protein  $\text{Fe}_4\text{S}_4$  cluster, was hard to reconcile with redox potentials of synthetic models. Indeed, a range of models with ligands differing by their charge, structure, and electron-withdrawing properties, has been studied electrochemically in dipolar aprotic organic solvent electrolytes (MeCN, DMF, DMSO) in order to assess the effect of the direct environment of the cluster core on its redox potentials.<sup>29</sup> The measured  $\Delta E$  between the  $2+/1+$  and  $1+/0$  redox potentials of model clusters remains consistently in the range ca.  $0.70 \pm 0.05 \text{ V}$  in organic

solvent electrolytes, and ca.  $0.40 \pm 0.02 \text{ V}$  in water. The reported absolute potential for the one-electron reduction of  $[\text{Fe}_4\text{S}_4]^{1+}$  in nitrogenase was also too high compared to model system values generally reported to be in the range  $-1.50$  to  $-1.85 \text{ V}$  (saturated calomel electrode (SCE)) in organic solvent electrolytes and ca.  $-1.2 \text{ V}$  (SCE) in water. Recently, the redox potential for the  $[\text{Fe}_4\text{S}_4]^{1+/0}$  couple of the iron-protein has been measured at  $-0.79 \text{ V}$  (NHE; i.e. ca.  $-1.03 \text{ V}$  SCE), corresponding to a  $\Delta E$  of  $0.48 \text{ V}$  between the two redox couples, more in line with experimental

and theoretical redox potential and associated  $\Delta E$  in model clusters.<sup>29,30</sup>

The polypeptide environment of the iron-protein  $\text{Fe}_4\text{S}_4$  cluster appreciably stabilizes the  $[\text{Fe}_4\text{S}_4]^0$  state compared to corresponding model clusters. This can be assigned to the network of hydrogen bonds between the protein residues and the cluster sulfide groups, and, to some extent, to the accessibility of water molecules to the cluster. However, the iron-protein iron–sulfur cluster in its  $[\text{Fe}_4\text{S}_4]^{1+}$  state does not appear to be reducible *in vivo* by known physiological electron donors, unless a currently unknown mechanism, such as a protein conformation change, stabilizes the  $[\text{Fe}_4\text{S}_4]^0$  state even more. Accurate synthetic models have helped to understand the structural, spectroscopic, and electronic properties of the  $\text{Fe}_4\text{S}_4$  cluster, particularly that of the iron-protein of nitrogenase. Whether or not the  $[\text{Fe}_4\text{S}_4]^0$  state is implied in the physiological electron transfer chain in nitrogenase remains to be proven. However, the sole fact that this latter state can be generated as a stable center within the protein encourages the quest for stable synthetic models in the all-ferrous state. These future models might bear a ligand scaffold mimicking the immediate stabilizing protein environment of the native cluster. In particular, it would be interesting to study the effect in terms of structure and associated electronic properties (electron transfer) of specific hydrogen bonds to the bridging sulfides as a function of the oxidation state of the cluster core. The modeling of a dielectric medium similar to the polarity and Lewis acidity experienced by iron–sulfur centers within proteins might be imposed by ligands sharing both covalent and noncovalent bonds to the cluster core. For recent progress towards the stabilization of the  $[\text{Fe}_4\text{S}_4]^0$  state and the measurement of the hydrogen bonding effect on the redox potential of  $\text{Fe}_4\text{S}_4$  clusters see references 73 and 74 respectively.

### 3 MODELS FOR THE $\text{Fe}_8\text{S}_7$ P-CLUSTER

Simple synthetic models for the active site of iron–sulfur proteins bearing centers of low nuclearity (one to four iron centers) have been relatively promptly synthesized and studied (see *Iron–Sulfur Models of Protein Active Sites*).<sup>27</sup> Centers of higher nuclearity however, such as the P-cluster or the FeMo-cofactor of the nitrogenase MoFe-protein, present a greater synthetic challenge not only because of their higher metal–sulfur content and structural complexity but also because faithful structural models were obtained only recently by protein crystallography. Recent progress in the artificial synthesis of the P-cluster core of nitrogenase is now discussed.<sup>31</sup>

The  $\text{Fe}_8\text{S}_7$  inorganic core of the P-cluster has been synthesized from tetramethylthiourea, 2,4,6-triisopropylbenzenethiol, elemental sulfur, and iron(II)bis(ditrimethylsilylamide) in toluene, in the respective 3/12/7/8 ratio (Figure 3a).<sup>32</sup> The

differences between the model and the native P-cluster lie within the nature of the ligands to the iron–sulfur sites, the iron atoms' oxidation states, and the shorter bond distances in the model around the central hexacoordinated sulfur. While the iron atoms are terminated or bridged by cysteinate ligands in the P-cluster, different ligations are involved in the model. Indeed, the two opposite apical iron sites of the synthetic cluster have a terminal bis-amide ligation, thiourea completes the tetrahedral coordination of two opposite central iron atoms, and the two remaining pairs of opposite iron centers are linked by a bis-amide bridge, as shown in Figure 3. The tighter amide bridge of the model compared to the cysteinate bridge found in the MoFe-protein explains the shorter  $\mu_6\text{S-Fe}$  bonds and shorter distance between opposite central iron atoms in the model.  $^{57}\text{Fe}$  Mössbauer spectroscopy of the model compound distinguishes two iron sites in a 3/1 ratio: each quadrupole doublet's isomer shift and quadrupole splitting are consistent respectively with 6 Fe(II) and 2 Fe(III), the former assigned to the six central iron atoms and the latter assigned to the two opposite apical iron centers. The oxidation state of the model (6 ferrous/2 ferric) is therefore directly related to that of the P-cluster in the  $\text{P}^{\text{OX}}$  state. Nevertheless, the structure of the  $\text{Fe}_8\text{S}_7$  core of the model resembles closely that of the  $\text{P}^{\text{N}}$  state, probably because the bridging amide prevents a more open structure similar to that of  $\text{P}^{\text{OX}}$ .

The model cluster has been reported to be very sensitive to oxygen and heat. This is consistent with the known instability of the P-cluster toward extraction from the MoFe-protein. Perhaps, for this reason no redox potentials were reported for the model. However, the current synthetic model (despite its different terminal and bridging ligands) provides the missing link for understanding the basic energetics of the electron transfer chain between the  $\text{Fe}_4\text{S}_4$  cluster, the P-cluster, and FeMo-co. Indeed, the redox potentials of  $\text{Fe}_4\text{S}_4$  clusters are well known both *in vivo* for the iron-protein  $\text{Fe}_4\text{S}_4$  cluster and in accurate synthetic or theoretical models.<sup>27,29,30</sup> The electrochemistry of the extracted FeMo-cofactor has also been studied in depth.<sup>33,34</sup> The knowledge of the detailed electrochemical properties of each metallo-cluster would also help to assess the extent of redox potential control by the surrounding supramolecular protein interactions and possible associated structural changes.

While the former model has been obtained by self-assembly from its basic components, the detailed step-by-step synthesis of topological analogues of the P-cluster has been reported (Figure 3c).<sup>31,35–38</sup> Cubane-like clusters with the  $[\text{MoFe}_3\text{S}_4]^{3+}$  or  $[\text{VFe}_3\text{S}_4]^{2+}$  core oxidation state and chloro ligands at Fe (see Section 4 for their synthesis) react respectively with phosphine and  $\text{NaBPh}_4$ , or phosphine only, to yield the phosphine-substituted  $[\text{MoFe}_3\text{S}_4]^{2+}$  and  $[\text{VFe}_3\text{S}_4]^{2+}$  clusters. Reduction of these phosphine-substituted cubane-like clusters yield edge-bridged double cubanes with the  $[\text{M}_2\text{Fe}_6\text{S}_8]^{2+}$  core ( $\text{M} = \text{Mo}$  or  $\text{V}$ ). Upon exposure to 3 or 4 equivalents of  $[\text{Et}_4\text{N}][\text{HS}]$ , the edge-bridged double cubanes rearrange into topological analogues of the  $\text{Fe}_8\text{S}_7$  P-cluster with the  $[\text{Mo}_2\text{Fe}_6\text{S}_7]^{5+}$  or

**Figure 3** (a) Synthesis of a P-Cluster analogue by self-assembly. (b) The structure of the P-Cluster in its native oxidation state ( $P^N$  state). (c) Stepwise synthesis of topological analogues of the P-cluster

$[\text{V}_2\text{Fe}_6\text{S}_7]^{4+}$  core respectively. Despite the heterogeneity of the metal content in the models, their inorganic cores are almost isostructural with the  $\text{Fe}_8\text{S}_7$  P-cluster in the  $\text{P}^{\text{N}}$  state. In addition, the bridging sulfides or terminal hydrosulfide ligands are closer analogues to the natural cysteinate ligations found in the MoFe-protein. It is proposed that such a rearrangement (of an all-iron edge-bridged double cubane) could be of relevance to the biosynthesis of the P-cluster of nitrogenase. A similar biosynthesis might be envisaged as well for the FeMo-cofactor provided two different cubes are condensed ( $\text{MoFe}_3\text{S}_4$  and  $\text{Fe}_4\text{S}_4$ ). However, according to the recent crystallographic analysis of the MoFe-protein, the central light atom is unlikely to be a sulfur atom.

#### 4 STRUCTURAL MODELS FOR THE $\text{MoFe}_7\text{S}_9$ FeMo-COFACTOR

As mentioned in the introduction, the crystallographic model of FeMo-co has been recently revised to include a light atom 'Y' at the center of the  $\text{Fe}_6$  trigonal prism.<sup>17</sup> Among the possible candidates for the light atom, nitrogen fits most closely to the experimental X-ray diffraction data,<sup>17</sup> and is also the choice of theoreticians.<sup>18–20</sup> If 'Y' is a nitrogen atom, a question remains as to whether it is a permanent structural component of FeMo-co or originates from dinitrogen itself and is included into the cluster framework at some stage of catalysis. It has been argued that if the interstitial nitrogen had to be released as ammonia before a new  $\text{N}_2$  molecule could bind to FeMo-co, then stoichiometric ammonia release should be detected after the transfer of three electrons. This is not consistent with available presteady state kinetic data.<sup>39</sup> In addition, spectroscopic investigations (by electron-nuclear double resonance and electron spin-echo envelope modulation) of both a wild type and a site-specifically altered nitrogenase MoFe-protein turning over  $^{14}\text{N}_2$  and  $^{15}\text{N}_2$ , led to the conclusion that, if the central atom in FeMo-co is N, then it is not an exchangeable nitrogen.<sup>40</sup>

These observations point toward a permanent structural role of an interstitial nitrogen atom at the center of FeMo-co, although this is not yet proven.

The revised version of the crystallographic FeMo-co model implies an obvious reappraisal of the synthetic structural modeling toward iron–sulfur nitride chemistry, a field that does not currently exist as such.<sup>41</sup>

It would be far from fair however, to say that structural modeling has to start from scratch again. Of course, the quest for tricoordinate iron–sulfur metal centers is no longer relevant to the biological catalysis,<sup>42</sup> although some of the low-coordinate complexes may be promising as abiological catalysts for dinitrogen reduction.<sup>43</sup> Many of the impressive array of MoFeS clusters, first developed long before the publication of the first crystallographic FeMo-co model remain highly pertinent to structural modeling.<sup>31,44–46</sup> Lessons from the biosynthesis of FeMo-co should also in principle help to define a synthetic strategy toward a cofactor model cluster. This process is however very complicated and not fully understood.<sup>47</sup> It is known that the cluster is assembled outside the MoFe-protein before being inserted. The maturation of FeMo-co goes through the mobilization of iron and sulfur (encoded by the NifU and NifS genes) and rearrangement to a Fe–S cluster called NifB-co (encoded by the NifB genes) of unknown structure. Mo (or V) and a homocitrate are inserted (or substituted) in this cluster at a later stage of maturation. A speculative proposal on the structure of NifB-co and its biosynthesis by cluster rearrangement has been put forward and is shown in Figure 4 (see also *Nitrogenase Catalysis & Assembly*).

The fragment of FeMo-co that has been most accurately modeled by synthetic clusters is its molybdenum cap. Indeed, cubane-like  $\text{MoFe}_3\text{S}_4$  clusters reproduce very well the first and second coordination sphere of molybdenum in nitrogenase.  $\text{MoFe}_3\text{S}_4$  clusters are usually synthesized from the double cubane  $[\text{Mo}_2\text{Fe}_7\text{S}_8(\text{SEt})_{12}]^{3-}$  (Figure 5) whose central iron bridge can be cleaved to yield independent  $\text{MoFe}_3\text{S}_4$  monocubes.<sup>31,44–46,48,49</sup> As shown in Figure 6, the use of encumbered chelators (e.g. tetrachlorocatecholate or dimethylphosphino ethane) is required to isolate independent cubes.<sup>48</sup> If less bulky chelators like catecholate or  $\pi$ -acceptor ligands like carbon monoxide or isocyanides are used, the

**Figure 4** Proposed core rearrangement of the NifB-cofactor (within a protein) intermediate in the biosynthesis of the FeMo and FeV-cofactor. The heterometal and homocitrate ligands are inserted at a later stage of biosynthesis, in a different protein

**Figure 5** Self-assembly synthesis of the iron-bridged double cubane  $[\text{Mo}_2\text{Fe}_7\text{S}_8(\text{SEt})_{12}]^{3-}$

iron-bridged double cubane is heterolytically cleaved to yield a  $\text{MoFe}_3\text{S}_4$  cube linked via Mo and thiolate bridges to an *exo*-Fe center.<sup>49</sup> When  $[\text{Mo}_2\text{Fe}_7\text{S}_8(\text{SEt})_{12}]^{3-}$  is left in solution (acetonitrile), it thermally evolves to the  $[\text{Mo}_2\text{Fe}_6\text{S}_8(\text{SEt})_9]^{3-}$  double cubane, demonstrating the inherent lability of the central iron bridge in  $[\text{Mo}_2\text{Fe}_7\text{S}_8(\text{SEt})_{12}]^{3-}$  and its great value as a synthon.

Alternatively, direct synthesis of  $\text{MoFe}_3\text{S}_4$  clusters is also possible from  $\text{TpMoS}(\text{S}_4)$ ,  $\text{FeCl}_2$ , and  $\text{NaSEt}/\text{PPh}_3$  (Tp is hydro(trispyrazolyl)borate(1-)) (Figure 7).<sup>50</sup> In addition to being a simpler synthetic procedure, the trigonal symmetry imposed at Mo by the Tp ligand also avoids isomeric mixtures when bridged  $\text{MoFe}_3\text{S}_4$  cubes are synthesized by the reaction of two single  $\text{MoFe}_3\text{S}_4$  cubes (see Section 2 on P-cluster modeling and references 31, 35–38 and 50).

Similarly,  $\text{VFe}_3\text{S}_4$  clusters are obtained by direct self-assembly from simple chemicals (ferrous chloride and tetrathiovanadate (Figure 7)).

Although the  $\text{MoFe}_3\text{S}_4$  cubes have not been found to interact with dinitrogen, some partial functional chemistry relevant to nitrogenase has been developed. First, in some examples where the Mo site is coordinated by a labile solvent molecule, it has been shown that the solvent ligand could be displaced by different unsaturated nitrogenase substrates. Examples with cyanide, azide, hydrazine, phenylhydrazine, or piperidine bound at Mo have been characterized by X-ray crystallography and/or by NMR spectroscopy.<sup>48</sup> Furthermore, these  $\text{MoFe}_3\text{S}_4$  with a labile solvent molecule at Mo catalyze the reduction of hydrazine to ammonia, of acetylene to ethylene and ethane, of *cis*-dimethyldiazene to methylamine, methane, and ammonia, or the disproportionation of hydrazine.<sup>44,51–54</sup> The involvement of the heterometal as the site of hydrazine reduction catalysis is strongly supported by: (1) inhibition experiments with inert ligands that bind to Mo like triethylphosphine, cyanide, or chloride; (2) much poorer catalysis results with related homometallic  $\text{Fe}_4\text{S}_4$  clusters; and (3) structural characterization of cubanes with hydrazine or phenylhydrazine bound at Mo. Likewise,  $[\text{VFe}_3\text{S}_4]^{2+}$  clusters catalyze the reduction of hydrazine to ammonia, and the rates of reduction correlate well with the availability of labile sites at the V atom.<sup>44,51,55</sup> Similar studies could also be envisioned with subsite-differentiated  $\text{Fe}_4\text{S}_4$  clusters to probe the catalytic properties of a single Fe-site of an all-iron

metal–sulfur cube in relation to the modeling of the all-iron nitrogenase.<sup>56</sup> Other  $\text{MoFe}_3\text{S}_4$  clusters with polycarboxylate ligation at molybdenum (e.g. citrate) were found to be even better catalysts than those with a more readily accessible metal site by labile solvent decooordination. This implies that the polydentate ligand partially decoordinates during catalysis and may further play the role of a proton shuttle for the bound substrate. It is tempting to relate these experimental observations to the presence of the bidentate homocitrate ligand at molybdenum in nitrogenase. More generally, this raises the question of the possible direct involvement in the biological reduction of dinitrogen (or at least at a later stage of catalysis, e.g. at the diazene or hydrazine reduction level), of the heterometal in  $\text{FeMo-co}$  and  $\text{FeV-co}$ , and perhaps as well of the corresponding apical iron atom in  $\text{FeFe-co}$ .<sup>44,51</sup> The possibility of partial decooordination of homocitrate from Mo, preceding  $\text{N}_2$  coordination at this metal, has been examined by molecular mechanics studies where the surrounding protein was taken into account.<sup>57</sup> It was found that *R*-homocitrate in its alkoxy monodentate form, is just of the right size to hydrogen bond via its longer ( $\text{C}_3$ ) free carboxylate arm to a neighboring lysine residue and to the imidazole ring from the histidine residue bound to Mo. The corresponding shorter ( $\text{C}_2$ ) arm of the closely related citrate ligand would not achieve this crucial interaction. Besides, (*R*)-homocitrate is known to be highly specific for biological nitrogen fixation, and mutated strains with a nitrogenase having citrate in place of (*R*)-homocitrate are much less efficient in reducing dinitrogen. The molecular mechanics study also showed that the medium ( $\text{C}_2$ ) free carboxylate arm of (*R*)-homocitrate interacts with a glycine residue, which creates a hydrogen bond path between the P-cluster and  $\text{FeMo-co}$ .<sup>34,57</sup> These theoretical and graphical studies of the X-ray structure of the  $\text{MoFe}$ -protein came in support of experimental stopped-flow kinetic studies of substrates binding to different types of the extracted  $\text{FeMo-cofactor}$ . One type is extracted from a wild bacterial strain where  $\text{FeMo-co}$  bears (*R*)-homocitrate at Mo. The other type is extracted from a mutated bacterial strain ( $\text{NifV}^-$ ) with citrate at Mo. The apical iron site of the extracted cofactors is coordinated by one solvent molecule (*N*-methyl formamide, NMF). This site binds a thiolate ligand ( $\text{PhS}^-$ ) with kinetics depending on what other ligands bind to the cluster. When cyanide, azide, or proton bind

**Figure 6** Reactivity of  $[\text{Mo}_2\text{Fe}_7\text{S}_8(\text{SEt})_{12}]^{3-}$ . Synthesis of  $\text{MoFe}_3\text{S}_4$  monocubes from  $[\text{Mo}_2\text{Fe}_7\text{S}_8(\text{SEt})_{12}]^{3-}$  (bottom)

**Figure 7** Direct synthesis of  $\text{MoFe}_3\text{S}_4$  and  $\text{VFe}_3\text{S}_4$  monocubes

to the cluster core, thiolate-binding kinetics to both types of cofactors are indistinguishable. However when imidazole binds to Mo, very different behaviors are observed. This was explained by specific H-bonding between (*R*)-homocitrate and imidazole. The binding of dinitrogen at the free Mo site has not been observed experimentally and remains a speculative proposal. It builds on earlier model studies with mononuclear molybdenum or tungsten phosphine dinitrogen complexes.<sup>58</sup> In some of these model complexes, a carboxylate ligand may act as a leaving group that opens a substrate binding site which coordinates  $\text{N}_2$ .<sup>58</sup>

When such molybdenum-dinitrogen complexes exist, the activation of  $\text{N}_2$  is always stronger for the tungsten analogue. Then, if the cofactor heterometal is indeed the site of dinitrogen activation, a FeW-cofactor may be even more efficient with respect to biological nitrogen fixation. Testing this hypothesis requires the isolation of a tungsten nitrogenase. This is not an easy task because of the presence of a highly specific Mo storage protein (in *Azotobacter vinelandii*) that contaminates with FeMo-co preparations grown on a tungstate medium, even when only traces of Mo are present. Besides, under Mo-deficient conditions, alternative nitrogenase systems may be expressed. Nevertheless, a tungsten (Mo-free) nitrogenase has recently been isolated under tungstate growth conditions from *Rhodobacter capsulatus*, that lacks a Mo-storage protein and whose mutated strain (*anfA*) is incapable of expressing the iron-only nitrogenase under molybdenum-deficient growth conditions.<sup>59</sup> The isolated tungsten-substituted nitrogenase was found to be only marginally active in reducing acetylene, and dinitrogen reduction was not observed. However, appreciable dihydrogen evolution was obtained, corresponding to a rate of ca. 25% of that observed for the native MoFe-protein. Redox titration of both proteins

showed the tungsten-substituted protein midpoint potential to be at least 150 mV more negative ( $< -200$  mV NHE) compared to that of the MoFe-protein ( $-50$  mV NHE). Hence, the FeW-co appears to be at least partially reducible to a state where hydrogen evolution occurs (but to a lesser extent than for FeMo-co), whereas the more reduced state where substrate activation occurs is not accessed. Considering thermodynamics alone, it is interesting to note that a functional iron-protein with a  $[\text{Fe}_4\text{S}_4]^0$  cluster would be a sufficiently strong reductant (ca  $-0.8$  V NHE) to reduce a tungsten-iron protein with  $E_{1/2}$  of approximately  $-0.3$  V NHE. Decreased hydrogen evolution would be advantageous for nitrogen fixation as discussed next, however the apparent impossibility of physiologically reducing the WFe-protein to a state where  $\text{N}_2$  would bind precludes any nitrogen fixation. This can be rationalized by two features of molybdenum and tungsten chemistry: (1) tungsten complexes or clusters are more difficult to reduce than their molybdenum analogues; (2) ligands are less labile at a tungsten center. Hence, even if FeW-co was reducible to the corresponding substrate binding redox state of FeMo-co, the partial decoordination of homocitrate from W might not occur because the breaking of a W–O bond requires more energy than for the corresponding Mo–O bond in FeMo-co.

Whether or not  $\text{N}_2$  binds at Mo, a possible role for this metal at the active site of the enzyme has been recently pointed out and is now discussed.<sup>60</sup> In the absence of  $\text{N}_2$ , all conventional nitrogenases reduce protons to dihydrogen. In the presence of  $\text{N}_2$ , only a fraction of electrons are used to reduce dinitrogen while the other fraction is still involved in dihydrogen formation, and is therefore wasted. The limiting stoichiometries for all three types of nitrogenase are as follows (equivalent of dihydrogen formed per equivalent

of reduced dinitrogen): Mo(1), V(3), and Fe(7.5). Hence, notwithstanding differences in the reduction mechanism and different protein structures, the presence of a heterometal in the iron–sulfur cofactor appreciably improves the efficiency of biological dinitrogen reduction, especially when this metal is molybdenum. The effect of Mo within a Fe–S cluster has been addressed experimentally by comparing the kinetics of proton binding to a  $\text{Fe}_4\text{S}_4$  cluster,  $[\text{Fe}_4\text{S}_4\text{Cl}_4]^{2-}$ , and a thiolate-bridged double  $\text{MoFe}_3\text{S}_4$  cluster:  $[\{\text{MoFe}_3\text{S}_4\text{Cl}_3\}(\mu\text{-SR}_3)]^{3-}$  ( $\text{R} = \text{Et}$  or  $\text{Ph}$ ).<sup>60</sup> The chloride ligands of these clusters are labile and can be substituted by nucleophiles such as thiolates. Protonation of Fe–S clusters, probably at the basic sulfide centers, is a known common reaction of such inorganic species. In the presence of a weak acid and a strong nucleophile such as thiophenolate, protonation of the cluster following thiolate binding is the rate-limiting step of the reaction with a similar rate constant for both types of  $\text{MFe}_3\text{S}_4$  clusters ( $\text{M} = \text{Fe}$  or  $\text{Mo}$ ). The rate of proton transfer to the cluster prior to nucleophile binding can be determined by measuring the kinetics of the reaction between the  $\text{MFe}_3\text{S}_4$  cluster and a poor nucleophile such as bromide, in the presence of a weak acid. Results show that proton transfer to any Fe–S cluster is slower in the absence of a bound nucleophile, and is about two orders of magnitude slower for  $\text{MoFe}_3\text{S}_4$  compared to  $\text{Fe}_4\text{S}_4$ . A simple electron-withdrawing effect of the heterometal seems excluded as the  $\text{pK}_a$  of protonated clusters falls into the narrow range of 18.9–17.9 and is little affected by the structure of the cluster. Rather, energetically more demanding bond length changes in Mo–Fe–S cluster are proposed as a possible explanation. Very interesting implications for biological dinitrogen fixation are then put forward. Because any dinitrogen binding site needs to be electron rich to ensure the ligand–metal  $\sigma$ -bonding and metal–ligand  $\pi$ -back bonding interactions, such sites may be easily protonated, which would then either decrease their affinity for dinitrogen or labilize an already bound  $\text{N}_2$  molecule. This could be avoided if electron transfer is also coupled to protonation, however this could also favor dihydrogen formation. Since proton transfer to Mo–Fe–S clusters is appreciably slower than to Fe–S clusters, the presence of molybdenum in the FeMo-cofactor could favor nitrogen fixation by enhancing the affinity of the binding site for dinitrogen and by slowing down the protonation of the cluster, which would also diminish or suppress unwanted dihydrogen evolution. Besides, model studies have shown that Mo–Fe–S clusters have a higher affinity than Fe–S cluster for binding species such as thiolates, halides, CO, or  $\text{N}_2\text{O}$ . Irrespective of the precise  $\text{N}_2$ -binding site at FeMo-co, molybdenum would make the enzyme a good nitrogenase and a poor hydrogenase, in agreement with the limiting stoichiometries reported for the Mo- and the all Fe-nitrogenase. It would be interesting to know if similar studies with  $\text{VFe}_3\text{S}_4$  clusters would yield a protonation rate constant in between those observed with  $\text{MoFe}_3\text{S}_4$  and  $\text{Fe}_4\text{S}_4$  clusters, which would be consistent with the known relative

$\text{N}_2$ -reduction efficiency of all three types of conventional nitrogenases ( $\text{Mo} > \text{V} > \text{Fe}$ ).

Current available cofactor models are hence only partially relevant in terms of structure: only the molybdenum/heterometal end of the cluster has been accurately modeled. In terms of functional relevance, no interactions with  $\text{N}_2$  have been obtained despite catalytic activation of reduced diazo species (e.g. hydrazine) or alternative substrates (e.g. acetylene). Considering the available biochemical data as well, one can only speculate on the precise site of  $\text{N}_2$  binding and reduction at FeMo-co, and on the exact role of the heterometal in this reaction. Electron-rich mononuclear molybdenum and tungsten complexes have been developed that bind dinitrogen and sometimes also support ammonia synthesis.<sup>34,58,61,62</sup> They are however structurally very different from FeMo-co for they are mononuclear and possess abiological ligands such as phosphine, permethylated cyclopentadienyl, or triamido amine. When more relevant sulfur ligands and/or metal–metal interactions were introduced, the key interaction with dinitrogen was lost in most cases although in some instances the activation of reduced diazo species was retained.<sup>34,62–66</sup> Theoretical assessments of possible  $\text{N}_2$  binding sites at FeMo-co can assist this debate, with the limitation that it is difficult to take into account theoretically the full structure of the active site (cluster, protein, and solvent molecules) and the afferent mechanistic complexity and subtleties of nitrogenase.<sup>18–20,34,62,67</sup> Irrespective of the  $\text{N}_2$  binding site considered, a general trend of theoretical calculations seems to be that FeMo-co is a rather weak  $\text{N}_2$  activator compared to well understood and efficient mononuclear systems. One must also keep in mind that the extracted FeMo-co itself does not interact with dinitrogen, which underlines the important role of the protein for  $\text{N}_2$  reduction by this center.

Given the current absence of interaction of any synthetic metal–sulfur cluster with dinitrogen, the binding of other and more reactive substrates or inhibitors of nitrogenase, like acetylene or carbon monoxide, are of interest. We have already pointed out that the heterometal site of  $\text{MoFe}_3\text{S}_4$  or  $\text{VFe}_3\text{S}_4$  cubes can support the reduction of acetylene. However, biochemical studies have established that acetylene is reduced on a specific  $\text{Fe}_4$  face of the central  $\text{Fe}_6$  trigonal prism of FeMo-co.<sup>68,75</sup> Besides, it is not known if acetylene and dinitrogen bind to the same site at FeMo-co, and these molecules probably bind with different FeMo-cofactor redox states. In any case, the current lack of structural models of the light atom-centered  $\text{Fe}_6$  trigonal prism precludes functional modeling of this site for the moment. Recent iron–sulfur imido chemistry might be of relevance to the activation of nitrogenous substrates by the central iron–sulfur core, but the development of iron–sulfur nitride chemistry is awaited.<sup>31,41,69</sup>

The future synthetic models of FeMo-co will have to closely resemble the now more accurate  $\text{MoFe}_7\text{S}_9\text{Y}$  crystallographic model (with ‘Y’ probably being N). The progress made in the synthesis of P-cluster analogues, discussed in the previous

section, is encouraging since the P-cluster has a similar size and metal–sulfur content as FeMo-co, although a bit less complex. The next challenge will be the development of some functional chemistry of relevance to nitrogenase at these future accurate FeMo-co models. Interaction of dinitrogen with these centers, a property that few molecular cluster have shown so far,<sup>3,70–72</sup> would be a breakthrough. It is evident that the task is not obvious taking into account: (1) the original and complex FeMo-co structure; (2) the rather weak affinity of FeMo-co for N<sub>2</sub> compared to model systems; (3) the complex mechanism of N<sub>2</sub> biological reduction coupled to the evolution of H<sub>2</sub>; and (4) the strong dependence of FeMo-co catalytic activity on the surrounding protein and specific amino acid residues, and on the (*R*)-homocitrate ligand. A synthetic functional peptide-FeMo-co center possessing the minimum structural and supramolecular requirements to activate N<sub>2</sub> could be a midterm goal.

## 5 CONCLUSIONS

Considerable progress in the synthesis of model clusters of nitrogenase has been made in recent years thanks to the continuous development in the laboratory of a rational and diverse iron–sulfur chemistry and to the increased knowledge of the natural systems themselves. The fact that biophysical and biochemical techniques now yield more detailed mechanistic and structural data on the enzymes may question the need for synthetic models. However, the advancement of the understanding of the mechanistic and structural complexity of the nitrogenase enzymes requires a multidisciplinary approach. Interactions and scientific debates between geneticists, biophysicists, biochemists, inorganic chemists, and theoretical chemists benefit all disciplines and scientists, and allow the knowledge of nitrogenases to advance at a faster pace. While the understanding of the enzyme advances, nitrogenase seems to challenge synthetic chemists regularly and the standards are set high. As discussed in this article, the scientific community has always taken up the challenge, sometimes brilliantly. For example, the [Fe<sub>4</sub>S<sub>4</sub>]<sup>2+/1+</sup> center of the iron-protein was thought to be well understood and modeled until this cluster was found to be stable in the [Fe<sub>4</sub>S<sub>4</sub>]<sup>0</sup> state within the protein. [Fe<sub>4</sub>S<sub>4</sub>]<sup>0</sup> synthetic models with thiolate ligands are all very unstable. Whether or not the [Fe<sub>4</sub>S<sub>4</sub>]<sup>0</sup> state is biologically relevant, which has to be clarified, the natural system gives the impetus to synthesize stable low-valent iron–sulfur centers and control their redox potentials by covalent and noncovalent binding. The two known structures of the P-cluster of nitrogenase show the importance of redox-linked structural flexibility of iron–sulfur clusters and the importance of the protein to stabilize them. The structure of the P-cluster in the native state can now be obtained in the laboratory by self-assembly, or topologically, in a stepwise and well-understood

fashion. Taking into account its astonishing structure and function alone, the FeMo-cofactor represents evidently the greatest challenge to modeling chemistry. This cluster is now known to be centered on a light atom that is probably a nitrogen atom, waiting to be identified with certainty. FeMo-co reduces dinitrogen with the help of the protein and its heterogeneous (*R*)-homocitrate ligand with an unknown intimate mechanism that also produces dihydrogen. Catalytic properties are retained when molybdenum is substituted with vanadium or iron in alternative nitrogenases. Considering these facts and, despite their inherent weaknesses, the prolific synthetic structural and functional models of the metal–sulfur centers of nitrogenases developed over the years, one could sum up the work in nitrogenase model clusters by ‘a lot done, more to do.’

## Abbreviations

MgATP = the magnesium complex of adenosine 5'-triphosphate; MgADP = the magnesium complex of adenosine 5'-diphosphate; P<sub>i</sub> = inorganic phosphate; MoFe protein = the molybdenum–iron protein of molybdenum nitrogenase; Fe protein = the iron protein of molybdenum nitrogenase; MgADP·AlF<sub>4</sub><sup>−</sup> = the magnesium complex of adenosine 5'-diphosphate and aluminum tetrafluoride; Cys = cysteine; FeMo cofactor = the iron–molybdenum cofactor of nitrogenase; P cluster = the [8Fe–7S] cluster of nitrogenase; P<sup>N</sup> = the dithionite-reduced state of P cluster; P<sup>OX</sup> = the two-electron oxidized state of P cluster; EPR = electron paramagnetic resonance; NMF = *N*-methylformamide; C<sub>2</sub>H<sub>2</sub> = acetylene; CS<sub>2</sub> = carbon disulfide; CO = carbon monoxide; Val = valine; Arg = arginine; *nif* = a molybdenum nitrogenase gene; VFe protein = the vanadium–iron protein of vanadium nitrogenase; *vnf* = a vanadium nitrogenase gene; MCD = magnetic circular dichroism; EXAFS = extended X-ray absorption fine structure spectroscopy; FeVa cofactor = the iron–vanadium cofactor of nitrogenase; FeFe protein = the iron–iron protein of iron-only nitrogenase; *anf* = an iron-only nitrogenase gene; FeFe cofactor = the iron–iron cofactor of nitrogenase; CO<sub>2</sub> = carbon dioxide; O<sub>2</sub><sup>•−</sup> = superoxide radical; H<sub>2</sub>O<sub>2</sub> = hydrogen peroxide.

## 1 INTRODUCTION

Nitrogenases represent a class of complex metalloenzymes that catalyze the process of biological N<sub>2</sub> fixation, during which dinitrogen is reduced to ammonia in a nucleotide-dependent process.<sup>1–12</sup> The ammonia produced is subsequently used for cell growth or maintenance. The overall reaction catalyzed by nitrogenases is usually depicted as follows:<sup>8,11,12</sup>

Nitrogenases are unique to bacteria, and animals or plants that fix N<sub>2</sub> must do so in association with bacteria.<sup>13</sup> Interest in nitrogenases arises from the importance of these enzymes to agriculture. Biological N<sub>2</sub> fixation provides roughly 90 million tons of N for agricultural soil each year and represents a major contributor of new N to agriculture and the food supply.<sup>8,10</sup> Meanwhile, attention has been drawn to the interesting chemistry involved in breaking the triple bond of the dinitrogen molecule under biological N<sub>2</sub> fixation conditions. How nitrogenases can carry out such an energy-demanding process under mild temperatures and pressures remains yet another driving force for research on these fascinating enzymes.

Four classes of nitrogenases have been described. They are the molybdenum nitrogenase (Sections 2–4), the vanadium nitrogenase (Section 5.1), the iron-only nitrogenase (Section 5.2), and the nitrogenase from *Streptomyces thermotrophicus* (Section 5.3). The major distinctive feature of the first three classes of nitrogenases, which are otherwise very similar, is the heterometal atom in the active site of the metal cluster (molybdenum, vanadium, or iron).<sup>5,8,10</sup> The fourth nitrogenase, however, is superoxide-dependent and apparently different from the other nitrogenase classes.<sup>14,15</sup>

Most of the current knowledge concerning the mechanism of nitrogenases is based upon extensive studies of the molybdenum nitrogenase; hence this enzyme will be the focus of discussion in this article. The general properties of the molybdenum nitrogenase are described in Section 2, and the catalytic and assembly mechanism of this enzyme system will be dealt with in Sections 3 and 4. The alternative nitrogenase systems will also be briefly discussed in Section 5.

## 2 MOLYBDENUM NITROGENASE

The molybdenum nitrogenase, undoubtedly the best-characterized form of nitrogenase, has been isolated from

a number of different microorganisms such as *Azotobacter vinelandii*, *Klebsiella pneumoniae*, and *Clostridium pasteurianum*.<sup>9,10,16</sup> Figure 1(a) is a schematic representation of the enzyme, which comprises two separately purifiable, oxygen-sensitive, metallosulfur proteins: the molybdenum-iron (MoFe) protein and the iron (Fe) protein, both of which are essential for enzymatic activity.<sup>1–12</sup> Figure 1(b) illustrates the substrate-reduction reaction of the molybdenum nitrogenase, a process in which the Fe protein forms a complex with the MoFe protein and acts as an obligate, MgATP-activated, electron donor for the MoFe protein, where the substrate is reduced (see also Section 3).<sup>2,3,7,9</sup>

## 2.1 The Fe Protein

The Fe protein, a member of the family of nucleotide-utilizing proteins (e.g. myosin, ras p21, recA),<sup>4,9</sup> is a

homodimer of  $M_r \sim 60$  kDa. The two identical subunits are encoded by the *nifH* gene, and there is a high degree of homology among the Fe proteins from a wide range of bacteria.<sup>10</sup> Each subunit of the Fe protein has a binding site for MgATP, and the two subunits are bridged by a [4Fe–4S] cluster (see *Iron–Sulfur Proteins*).<sup>1–4,6–9,17–20</sup>

### 2.1.1 Protein Structure

The X-ray crystal structures of several conformations of the Fe protein, either alone or in complex with the MoFe protein, have been solved.<sup>21–27</sup> Figure 2 shows the MgADP-bound conformational state of the Fe protein of *A. vinelandii*,<sup>10,26</sup> where each subunit folds as a single  $\alpha/\beta$ -type domain and the subunits together symmetrically ligate the surface-exposed [4Fe–4S] cluster through two cysteines from each subunit. Two MgADP molecules are

**Figure 1** Schematic representation of the molybdenum nitrogenase (a) and the substrate-reduction reaction of the molybdenum nitrogenase (b) and alternative nitrogenases (c)

**Figure 2** Structure of the  $\alpha_2$  homodimeric Fe protein of *A. vinelandii*, with the subunits colored in light and dark gray. The polypeptide chains are shown in ribbon presentation, and the [4Fe–4S] cluster and the two bound MgADP are shown in space-filling representation. PDB entry 1FP6 and programs MOLSCRIPT<sup>29</sup> and RASTER3D<sup>30</sup> were used to generate this figure

bound in a parallel orientation relative to each other near the dimer interface, one on each subunit. The nucleotide binding sites are located approximately 15 Å away from the [4Fe–4S] cluster and the docking surface between the Fe protein and the MoFe protein, indicating that the bound nucleotides need to exert their effects on the nitrogenase catalytic cycle from a distance through conformational changes.<sup>6,9,19</sup> The exact structure of the Fe protein in the MgATP-bound conformation is unknown, though X-ray scattering data have shown that the conformational changes of the Fe protein upon MgATP binding cause a contraction of the protein by 2.0 Å on average.<sup>28</sup> The same contraction is observed in the structure of the Fe protein in complex with the MoFe protein and MgADP·AlF<sub>4</sub><sup>–</sup>,<sup>21</sup> suggesting that the MgATP-bound conformation of the isolated Fe protein is similar to that of the Fe protein in this complex structure. The structural details of the Fe protein involved in the catalytic mechanism will be discussed in Section 3.1.

### 2.1.2 The [4Fe–4S] Cluster

The [4Fe–4S] cluster is exposed to solvent and is symmetrically bridged between the two subunits of the Fe protein by the side chains of Cys97 and Cys132 (Figure 3).<sup>3,10</sup> The cluster ligands are located near the N termini of  $\alpha$ -helices that are directed toward the cluster, permitting favorable electrostatic interactions between the terminal amide groups of the helices and the anionic cluster.<sup>10</sup> The [4Fe–4S] cluster of the Fe protein can exist in three different oxidation states,<sup>10,25</sup> that is, [4Fe–4S]<sup>2+</sup>, [4Fe–4S]<sup>1+</sup>, and [4Fe–4S]<sup>0</sup> (see *Iron–Sulfur Proteins*). The physiological relevance of the various oxidation states of

**Figure 3** Structure of the [4Fe–4S] cluster of the *A. vinelandii* Fe protein including the coordinating ligands Cys97 and Cys132 from both subunits of the Fe protein (indicated as \* and \*\*). Iron and sulfur atoms are colored in dark and light gray, respectively. PDB entry 2NIP and programs MOLSCRIPT<sup>29</sup> and RASTER3D<sup>30</sup> were used to generate this figure

the [4Fe–4S] cluster will be discussed in greater detail in Section 3.1.

## 2.2 The MoFe Protein

The MoFe protein is an  $\alpha_2\beta_2$  tetramer of  $M_r \sim 220$  kDa, and its  $\alpha$  and  $\beta$  subunits are encoded by the *nifD* and *nifK* gene, respectively (Figure 1(a) and Table 1).<sup>7,9,10</sup> It contains, in preparations with the highest activity, 2 molybdenum (Mo),  $\sim 30$  to 34 iron (Fe), and an approximately equivalent number of acid-labile sulfur (S<sup>2–</sup>) atoms (Table 1).<sup>5,16</sup> This metal content is consistent with the presence of two different types of unique metal clusters in the protein, that is, the [8Fe–7S] cluster (P cluster), which is bridged between each  $\alpha\beta$  subunit pair, and the [Mo–7Fe–9S–homocitrate] cluster (FeMo cofactor or FeMoco), which is located within each  $\alpha$  subunit (Figure 1a).<sup>9,10,17</sup>

### 2.2.1 Protein Structure

The X-ray crystal structures of MoFe protein, alone or in complex with the Fe protein, have been reported for *A. vinelandii*,<sup>21,22,37–43</sup> *C. pasteurianum*,<sup>44,45</sup> and *K. pneumoniae*,<sup>46,47</sup> and all of these structures are highly conserved on the basis of both primary sequence and three-dimensional structure. The MoFe protein of *A. vinelandii* is an  $\alpha_2\beta_2$  heterotetramer consisting of a pair of  $\alpha\beta$  dimers related by a molecular twofold rotation axis (Figure 4).<sup>3,37,38</sup> The homologous  $\alpha$  and  $\beta$  subunits include three domains, designated  $\alpha$ I,  $\alpha$ II, and  $\alpha$ III and  $\beta$ I,  $\beta$ II, and  $\beta$ III, respectively, all of which exhibit parallel  $\beta$ -sheet/ $\alpha$ -helical type of polypeptide folds. Domains of both subunits contribute ligands to the P cluster. These ligands are located in a common core of a four-stranded, parallel  $\beta$ -sheet flanked by  $\alpha$ -helices and additional  $\beta$ -strands.<sup>7</sup> The P clusters are located between

**Table 1** Comparison of the catalytic and biophysical properties of MoFe, VFe, and FeFe proteins<sup>5,8,16,31–36</sup>

|                                                                            | MoFe protein               |                            | VFe protein                               |                                           |                                           | FeFe protein                              |                                           |                                           |

<sup>a</sup>Metal content in mol metal/mol protein. <sup>b</sup>ND = not determined. <sup>c</sup>Specific activities in nmol/min/mg protein. <sup>d</sup>These activities were originally reported in nmol/assay. The conversion of these values for the table are based on the reported assay conditions (assay time: 1 h; amount of FeFe protein: 0.92 mg).<sup>33</sup> Av = *Azotobacter vinelandii*; Kp = *Klebsiella pneumoniae*; Ac = *Azotobacter chroococcum*; Rc = *Rhodobacter capsulatus*; Rr = *Rhodospirillum rubum*. Note that the component proteins of the nitrogenase are often designated by the initials of the organism from which they were isolated and the arabic numeral of the component. For example, Av1 is the MoFe protein of *A. vinelandii* and Kp2 is the Fe protein from *K. pneumoniae*.<sup>3,5,10</sup> This nomenclature is also applied to the alternative nitrogenases, with the addition of a superscript “V” or “Fe” to indicate whether the component protein is from the vanadium or iron-only nitrogenase system. For example, Av1<sup>V</sup> is the VFe protein of *A. vinelandii* and Rr2<sup>Fe</sup> is the Fe protein from *R. rubum*. For the purpose of simplicity, this nomenclature is not used in this article, though readers may find it useful when reading some of the nitrogenase-related literature.

**Figure 4** Structure of the  $\alpha_2\beta_2$  tetrameric MoFe protein of *A. vinelandii*, with the  $\alpha$  and  $\beta$  subunits colored in light and dark gray, respectively. The polypeptide chains are shown in ribbon presentation, and the FeMo cofactors and P clusters are shown in space-filling representation. PDB entry 1M1N and programs MOLSCRIPT<sup>29</sup> and RASTER3D<sup>30</sup> were used to generate this figure

domains  $\alpha$ I and  $\beta$ I, whereas the FeMo cofactor occupies a cavity within the MoFe protein, formed among domains  $\alpha$ I,  $\alpha$ II, and  $\alpha$ III.

### 2.2.2 P Cluster

The P cluster is found at the interface between the  $\alpha$  and  $\beta$  subunits, 10 Å below the surface of the protein.<sup>7,10,48</sup>

When the MoFe protein is isolated in the presence of excess dithionite, its P cluster is in an  $S = 4$ , diamagnetic state (designated  $P^N$ ).<sup>4,49,50</sup> All of the iron atoms of the  $P^N$  state are believed to be ferrous. There is some indication of the possible presence of some ferric character in this diamagnetic state, though there is no experimental evidence that the P cluster can be reduced further to an oxidation state below  $P^N$ . On the other hand, the  $P^N$  state of the P cluster can be two-electron oxidized to the  $P^{2+}$  state (designated  $P^{OX}$ ) with dye oxidants thionine or indigodisulfonate (IDS).<sup>51</sup> This stable  $S = \text{integer}$  (3 or 4) state can be recognized by a  $g = 11.8$  signal observed in the parallel mode EPR.<sup>49,52</sup> In addition to  $P^N$  and  $P^{OX}$ , a mixed  $S = 1/2 : S = 5/2$  state of the P cluster has been characterized<sup>53</sup> and is believed to represent  $P^{1+}$ , the one-electron oxidation product of  $P^N$ . The P cluster is proposed to be involved in the electron transfer during the substrate-reduction reaction (see also Section 3.2), though its exact function in this process is not clear (see *Iron-Sulfur Proteins*).

Figure 5 shows the structures of  $P^N$  and  $P^{OX}$ . Both states of the P cluster contain eight iron and seven sulfur atoms, which are covalently coordinated to the MoFe protein by six cysteinyl ligands, three from the  $\alpha$ -subunit, that is, Cys  $\alpha$ 62, Cys  $\alpha$ 88, and Cys  $\alpha$ 154, and three from the  $\beta$ -subunit, that is, Cys  $\beta$ 70, Cys  $\beta$ 95, and Cys  $\beta$ 153. In both cases, Cys  $\alpha$ 62, Cys  $\alpha$ 154, Cys  $\beta$ 70, and Cys  $\beta$ 153 coordinate one iron atom each,

**Figure 5** Structure of the (a) dithionite-reduced ( $P^N$ ) and (b) two-electron-oxidized ( $P^{OX}$ ) state of the P cluster of the *A. vinelandii* MoFe protein including the coordinating ligands. Iron and sulfur atoms are colored in dark and light gray, respectively. PDB entries 1M1N ( $P^N$ ) and 2MIN ( $P^{OX}$ ) and programs MOLSCRIPT<sup>29</sup> and RASTER3D<sup>30</sup> were used to generate this figure

whereas Cys  $\alpha 88$  and Cys  $\beta 95$  coordinate two iron atoms each.<sup>37,38,40</sup> However,  $P^N$  and  $P^{OX}$  are structurally different in that one half of the P cluster in the  $P^{OX}$  state is present in a more open conformation.<sup>10</sup> The interconversion between  $P^N$  and  $P^{OX}$  involves two iron atoms of the P cluster, and the changes in the core structure of the cluster are accompanied by the changes in the ligation between the cluster and the protein.<sup>40</sup> Two additional protein ligands are present in the  $P^{OX}$  state, one is the  $O\gamma$  of Ser  $\beta 188$  that coordinates the same iron atom as the cysteinyl group of Cys  $\beta 153$ , whereas the other is the Cys  $\alpha 88$  that coordinates an iron with a backbone amide nitrogen ligand in addition to providing a cysteinyl ligand to the same iron atom (Figure 5).<sup>40</sup>

### 2.2.3 FeMo Cofactor

The FeMo cofactor is located within the  $\alpha$  subunit of the MoFe protein, 14 Å away from the P cluster. It can be studied when it is buried within the MoFe protein or extracted into *N*-methylformamide (NMF).<sup>3,4,18,54</sup> The FeMo cofactor can undergo reversible one-electron oxidation and reduction,<sup>4</sup> and it is generally accepted that the FeMo cofactor provides the site for substrate reduction. The redox properties of the FeMo cofactor and their physiological relevance will be discussed further in Section 3.2.

Figure 6 shows the structure of the FeMo cofactor.<sup>42</sup> It has the overall stoichiometry of Mo : Fe<sub>7</sub> : S<sub>9</sub> : homocitrate and is composed of a [4Fe–3S] cluster and a [Mo–3Fe–3S] cluster bridged by three inorganic sulfide atoms.<sup>37–39,42,44–46,48</sup>

**Figure 6** Structure of the FeMo cofactor of the *A. vinelandii* MoFe protein including the coordinating ligands Cys  $\alpha 275$  and His  $\alpha 442$ . Molybdenum, iron, and the central ligand (plausibly nitrogen) are colored in dark gray, with a decrease in atomic radii in the order of Mo > Fe > central ligand. Sulfur is colored in light gray. PDB entry 1M1N and programs MOLSCRIPT<sup>29</sup> and RASTER3D<sup>30</sup> were used to generate this figure

A recently resolved high-resolution (1.16 Å) structure of the *A. vinelandii* MoFe protein revealed the possible presence of a nitrogen atom that is coordinated to six iron atoms in the center of the FeMo cofactor (Figure 6),<sup>42</sup> though conclusive evidence for the identity of this atom remains to be obtained. The core charge of the metals in the FeMo cofactor is proposed to be +1<sup>55</sup> or +3<sup>56</sup> in the resting state, yet the isolated FeMo cofactor is known to be anionic.<sup>4</sup> The overall negative charge of the FeMo cofactor is supplied by homocitrate, an organic terminal ligand of molybdenum, which is −4 if the −OH is deprotonated. The cofactor is ligated to the  $\alpha$  subunit of the MoFe protein by just two ligands, His  $\alpha$ 442 and Cys  $\alpha$ 275 (Figure 6).

### 3 NITROGENASE CATALYSIS

The most comprehensive model for the function of molybdenum nitrogenase in the reduction of  $N_2$  is that of Lowe and Thorneley, which was developed almost two decades ago.<sup>57</sup> This model describes two aspects of nitrogenase catalysis, the Fe protein cycle and the MoFe protein cycle.

#### 3.1 Fe Protein Cycle: Electron Transfer from the Fe Protein to the MoFe Protein in the Nitrogenase Complex

Figure 7 shows what is believed to occur during the one-electron Fe protein cycle of the molybdenum nitrogenase, the process in which the Fe protein serves as an obligate electron donor for the MoFe protein.<sup>4,8,10,57,58</sup> In order to carry out the catalytic function of nitrogenase, the reduced Fe protein first binds two molecules of MgATP and undergoes a conformational change before forming a complex with the MoFe protein. Then, coupled with the hydrolysis of 2MgATP molecules to 2MgADP and 2P<sub>i</sub>, one electron is transferred

**Figure 7** The Fe protein cycle of the molybdenum nitrogenase.<sup>4,8,10,57,58</sup> The cycle describes the MgATP-dependent electron transfer from the Fe protein (F) to one  $\alpha\beta$  half of the MoFe protein (M), which is accompanied by the hydrolysis of 2MgATP to 2MgADP and 2P<sub>i</sub>. Subscripts: ox = oxidized and red = reduced

from the [4Fe–4S]<sup>1+</sup> cluster of the Fe protein to the MoFe protein within the complex. This process is followed by complex dissociation, re-reduction of the oxidized Fe protein, and the dissociation of MgADP, which allows the enzyme complex to start the next cycle of electron transfer.

The distances between the nucleotide binding sites of the Fe protein, the [4Fe–4S] cluster, and the Fe protein/MoFe protein interface (Section 2.1.1) suggest that conformational changes are involved in the catalytic mechanism of the nitrogenase.<sup>6,9,19</sup> Mutagenic studies show that the initial conformational change of the Fe protein, which occurs upon MgATP binding, involves the Walker A motif or the phosphate-binding loop (P-loop), two switch regions (Switch I and II), and a region around residue A157. The Walker A motif and Switch I and II are characteristic of the G-protein family, whereas the area around A157 is unique to the Fe protein.<sup>6,10,19,59–61</sup> In the MgADP-bound conformation of the *A. vinelandii* Fe protein, the Walker A motif (residues 9–16, GKGGIGKS, consensus residues underlined) forms a loop that wraps around the phosphate groups of the nucleotide, with the hydroxyl of residue 16 coordinating the Mg<sup>2+</sup> ion and the invariant lysine forming a salt bridge with the  $\beta$  phosphate. It is therefore proposed that Switch I (residues 38–44) provides direct communication links between the nucleotide binding site and the MoFe protein docking interface, whereas Switch II (residues 125–129) is responsible for signal transduction between the nucleotide binding site and the [4Fe–4S] cluster.<sup>9,10</sup>

Three oxidation states (0, +1, and +2) have been reported for the [4Fe–4S] cluster of Fe protein (Section 2.1.2).<sup>10,25</sup> Figure 8(a) shows the EPR spectrum of the dithionite-reduced [4Fe–4S]<sup>1+</sup> cluster of the Fe protein in the absence of nucleotides that exhibits an S = 1/2 signal in the g = 2 region with a rhombic line shape,<sup>4,62,63</sup> whereas Figure 8(b) shows the EPR-silent spectrum that arises from the diamagnetic IDS-oxidized [4Fe–4S]<sup>2+</sup> cluster of the Fe protein.<sup>64</sup> The E<sup>0'</sup> of the [4Fe–4S]<sup>2+/1+</sup> couple of Fe protein is −310 mV versus NHE, which becomes ca. 100 mV more negative in

**Figure 8** EPR spectra of (a) dithionite-reduced and (b) IDS-oxidized Fe protein in the absence of nucleotide.<sup>4,62–64</sup> The spectra were recorded at 13 K. Note that the dithionite-reduced Fe protein exists in a mixture of S = 1/2 and S = 3/2 spin states.<sup>18</sup> Only the S = 1/2 EPR signal in the g = 2 region is shown in the figure

the presence of MgATP.<sup>4</sup> It has been shown that ferredoxin or flavodoxin in vivo or dithionite in vitro can reduce the [4Fe–4S] cluster of the Fe protein to the +1 state (Figure 1b), and the [4Fe–4S]<sup>2+/1+</sup> couple is believed to be utilized in the Fe protein cycle under physiological conditions. However, it has also been demonstrated that the [4Fe–4S] cluster can be further reduced, reversibly, to the all-ferrous [4Fe–4S]<sup>0</sup> state<sup>25,64</sup> and that two electrons can be transferred from this state to the MoFe protein concomitant with the hydrolysis of two molecules of MgATP,<sup>65</sup> leading to the suggestion that the [4Fe–4S]<sup>2+/0</sup> couple is utilized in vivo at least under some circumstances. In addition to that, a midpoint potential of –800 mV versus NHE has been described recently for the [4Fe–4S]<sup>1+/0</sup> couple.<sup>66</sup> Nevertheless, the physiological relevance of the all-ferrous state of the Fe protein is yet to be established.

### 3.2 The MoFe Protein Cycle: Electron Transfer within the MoFe Protein and the Substrate-reduction Reaction

Figure 9 shows the MoFe protein cycle, which consists of eight one-electron transfer steps, each of which corresponds to one Fe protein cycle.<sup>4,8,10,57,58</sup> The reactions shown in Figure 9 are consistent with the overall stoichiometry of the enzymatic N<sub>2</sub> reduction, that is,  $\text{N}_2 + 8\text{H}^+ + 8\text{e}^- \rightarrow 2\text{NH}_3 + \text{H}_2$ .<sup>10</sup>

Following the transfer of one electron from the Fe protein to the MoFe protein, the FeMo cofactor, which is present in an  $S = 3/2$  state with unique features at  $g = 3.65$  and  $2.01$  (Figure 10a), is reduced to an EPR-silent but paramagnetic state.<sup>4</sup> The disappearance of this EPR signal, which can also be accomplished chemically by oxidation with thionine (Figure 10b),<sup>4,64</sup> occurs after the addition of one electron to one FeMo cofactor, indicating that the FeMo cofactor is the final location for the first electron that enters the MoFe protein

**Figure 10** EPR spectra of (a) dithionite-reduced and (b) thionine-oxidized MoFe protein of *A. vinelandii*. The  $S = 3/2$  EPR signal arises from the FeMo cofactor center of the protein.<sup>4,8,10,18,64,67–69</sup> The spectra were recorded at 10 K

from the Fe protein. The MgADP·AlF<sub>4</sub><sup>–</sup>-stabilized complex between the Fe protein and the MoFe protein, which is believed to represent the transition state during MgATP hydrolysis, provides some compelling evidence that the electrons are transferred from the Fe protein to first the P cluster and then the FeMo cofactor (Figure 11).<sup>21</sup> Following that, it is believed that electrons are transferred from the FeMo cofactor to the bound substrate, and the substrate reduction subsequently takes place. Interestingly, it has been observed that all products leaving the nitrogenase are reduced by multiples of two electrons. Therefore, the MoFe protein must be able to accumulate several electrons before products are released. Currently, it is not known whether the electrons are stored in the P cluster, the FeMo cofactor, or the enzyme-bound intermediate of substrate reduction. Also, direct evidence that suggests how

**Figure 9** The MoFe protein cycle of the molybdenum nitrogenase.<sup>4,8,10,57,58</sup> The cycle describes a plausible sequence of events during the reduction of N<sub>2</sub> to 2NH<sub>3</sub> and H<sub>2</sub>. M represents one functional half of the MoFe protein, which is composed of one  $\alpha\beta$  subunit pair plus one FeMo cofactor and one P cluster. Subscripts 0 to 7 indicate the number of electrons transferred to M from the Fe protein via the Fe protein cycle. It is plausibly assumed that each transferred electron is neutralized by the addition of one proton. Each dotted arrow corresponds to one completed Fe protein cycle (shown in Figure 7)

**Table 2** Substrates and inhibitors of nitrogenase<sup>4,8,58,83</sup>

| Substrate/inhibitor           | Reaction catalyzed by nitrogenase                                                                                                                            |

**Figure 11** The relative positions of the components of the ADP·AlF<sub>4</sub><sup>−</sup>-stabilized complex that are involved in the electron flow during the substrate-reduction reaction. PDB entry 1M34 and programs MOLSCRIPT<sup>29</sup> and RASTER3D<sup>30</sup> were used to generate this figure. Metal clusters and ADP·AlF<sub>4</sub><sup>−</sup> are shown in space-filling representation. In addition, residues 8 to 20 (including the Walker A motif) and 125 to 135 (including Switch II) from both subunits of the Fe protein are shown (indicated as \* and \*\*). Electrons flow in a MgATP-dependent reaction from the [4Fe–4S] cluster of Fe protein to first the P cluster and then the FeMo cofactor of the MoFe protein, where the reduction of dinitrogen to ammonia occurs

the substrate might bind to the FeMo cofactor site of the enzyme, where substrate reduction takes place, is limited. Furthermore, though it is known that the substrate-reduction reaction involves an equal number of electrons and protons and that the P cluster might be involved in this process,<sup>9,40</sup> how protons are transferred from the solvent to the FeMo cofactor site has not been established.

What is known, though, is that in addition to its physiological substrates, that is, N<sub>2</sub> and H<sup>+</sup>, nitrogenase is able to reduce a large variety of small doubly and triply bonded substrates (Table 2). Progress has been made in understanding the interaction of the FeMo cofactor site with such substrates or inhibitors as C<sub>2</sub>H<sub>2</sub>, CS<sub>2</sub>, or CO,<sup>55,70–75</sup> as well as that of the isolated FeMo cofactor with CN<sup>−</sup> and CO.<sup>76–80</sup> Also, on the basis of a molecular biology approach, it has been suggested that the substrate might bind to the [4Fe–4S] face of the FeMo cofactor, which is capped by Val α70 and Arg α96 of the MoFe protein.<sup>81,82</sup> In addition, as mentioned in Section 2.2.3, a high-resolution (1.16 Å) structure of the nitrogenase MoFe protein has been obtained recently, which indicates the possible presence of a nitrogen atom that is coordinated to six iron atoms in the center of the FeMo cofactor.<sup>42</sup> This interesting finding may in time provide us with significant insight into the mechanism of dinitrogen reduction.

#### 4 NITROGENASE ASSEMBLY

The biosynthesis of nitrogenase is arguably one of the most complex processes in the field of bioinorganic chemistry, requiring the participation of at least 15 different gene

products. Like Section 3, this section will only discuss the assembly mechanism of the molybdenum nitrogenase, which is the best-characterized nitrogenase system.

#### 4.1 Fe Protein Assembly

The assembly of the Fe protein involves the biosynthesis of the structural polypeptides and the biosynthesis and insertion of the [4Fe–4S] cluster into the Fe protein. Substantial progress has been made in understanding the assembly of the molybdenum nitrogenase Fe protein and its [4Fe–4S] cluster, a process that involves the *nifH* gene that encodes for the subunits of the Fe protein and at least *nifS*, *nifU*, and *nifM* gene products that are implicated in the [4Fe–4S] cluster assembly (Table 3 and Figure 12).<sup>8,11,84</sup> It was initially proposed that NifS (*nifS* gene product) and NifU (*nifU* gene product) have complementary functions related to the general mobilization of S and Fe for nitrogenase metallocluster formation. This suggestion was supported by experiments that demonstrated that NifS is a pyridoxal-dependent cysteine desulfurase and that NifU provides an in vitro scaffold for the formation of [2Fe–2S] clusters destined for nitrogenase metallocluster formation.<sup>85–87</sup> A likely pathway involves the formation of a protein-bound cysteine persulfide on NifS that is subsequently donated to NifU, upon which, in the presence of Fe, a labile [2Fe–2S] cluster is formed.<sup>88</sup> The exact mechanism concerning the assembly of [2Fe–2S] units on the NifU scaffold is not clear, nor is the issue of whether [2Fe–2S] or [4Fe–4S] units are ultimately formed on the NifU scaffold prior to their release for Fe protein maturation. In contrast to the emerging information of the role of NifS and NifU in the Fe protein assembly, little is known about the function of NifM (*nifM* gene product), which has been shown to be essential for the process.<sup>8</sup>

#### 4.2 MoFe Protein Assembly

The assembly of the MoFe protein involves the biosynthesis of the FeMo cofactor, and in a separate pathway, the biosynthesis of a P cluster-containing yet FeMo cofactor-deficient species of the MoFe protein and the insertion of the completed FeMo cofactor into the FeMo cofactor-deficient MoFe protein.<sup>2,8,18,67,69,89</sup>

##### 4.2.1 Biosynthesis of the FeMo Cofactor

Figure 12 illustrates the current model of FeMo cofactor biosynthesis, a process independent of the production of MoFe protein polypeptides,<sup>91–93</sup> which starts with the mobilization of iron and sulfur and the assembly of Fe/S fragments by NifS and NifU.<sup>11</sup> These Fe/S fragments are transferred to NifB (*nifB* gene product),<sup>84</sup> which is subsequently involved in the production of the Fe/S core of the FeMo cofactor (designated NifB cofactor) that probably contains all of

the iron and sulfur that ends up in the FeMo cofactor (Table 3).<sup>94,95</sup> Following that, the NifB cofactor, probably bound to an ‘escort’ protein designated NifX (*nifX* gene product), binds to a scaffold NifN<sub>2</sub>E<sub>2</sub> protein (encoded by the *nifN* and *nifE* gene products).<sup>84,96–100</sup> It is possible that molybdenum and homocitrate could be incorporated into the NifB cofactor while it is attached to NifX in a process that possibly involves NifW and NifV<sup>84,101,102</sup> (*nifW* and *nifV* gene products, respectively). Subsequently, at the transient NifN<sub>2</sub>E<sub>2</sub> scaffold, the NifB cofactor is rearranged by an unknown mechanism and forms the completed FeMo cofactor. The process of FeMo cofactor formation also requires the Fe protein, MgATP, and reductant,<sup>103–105</sup> though their exact functions in the process have not been established. The completed FeMo cofactor is then transferred to another ‘escort’ protein, probably NifY that is encoded by the *nifY* gene in *K. pneumoniae*<sup>106</sup> or the non-*nif*-encoded protein called gamma ( $\gamma$ ) in *A. vinelandii*,<sup>107</sup> which delivers the FeMo cofactor to the FeMo cofactor-deficient MoFe protein (see also Section 4.2.3). However, the exact function of  $\gamma$  in the MoFe protein assembly remains unknown, and the essential role of  $\gamma$  in the process was questioned very recently.<sup>108</sup>

##### 4.2.2 Biosynthesis of a P Cluster-containing, FeMo Cofactor-deficient MoFe Protein

As shown in Figure 12, the biosynthesis of the P cluster-containing yet FeMo cofactor-deficient MoFe protein involves *nifD* and *nifK*, which encode the  $\alpha$  and  $\beta$  subunit of the MoFe protein, respectively, and at least the *nifS* and *nifU* gene products, in addition.<sup>8</sup> Expression of the molybdenum nitrogenase is activated by molybdenum and regulated by *nifA* and *nifL* (Table 3). Little is known about the assembly mechanism of the P cluster. Nonetheless, such a P cluster-containing but FeMo cofactor-deficient MoFe protein is obtained from a *nifB* deletion strain of *A. vinelandii*, and an isolated FeMo cofactor can be readily inserted into this MoFe protein.<sup>109</sup> The X-ray crystal structure of this cofactor-deficient protein provides interesting insights into the FeMo cofactor insertion and MoFe protein maturation process<sup>43</sup> and will be discussed in greater detail in the following section.

##### 4.2.3 Insertion of the FeMo Cofactor into the FeMo Cofactor-deficient MoFe Protein

Like the biosynthesis of the FeMo cofactor (Section 4.2.1), the insertion of the FeMo cofactor into the FeMo cofactor-deficient form of the MoFe protein also requires the presence of the Fe protein.<sup>2,4,8,18,67,69,89</sup> This final maturation process of the MoFe protein most likely occurs in a series of steps, which are shown in Figure 12. Initially, the FeMo cofactor site is not accessible to FeMo cofactor insertion (‘closed’ conformation).<sup>105,110,111</sup> The conversion of this site to another form with the FeMo cofactor site accessible to

**Table 3** The *nif* gene products and functions<sup>1,4,8,10,11,69,82–84,87,89,90</sup>

| Gene                               | Product/function                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

| <i>nifV<sup>a</sup></i>            | Product: Homocitrate synthase.<br>Function: Formation of homocitrate, which is the organic component of the FeMo cofactor.                                                                                                                                                                                                                                                                                                                                                                                                       |
| <i>nifX</i>                        | Product: NifX.<br>Possible function: NifX can bind the FeMo cofactor or NifB cofactor. Might be an intermediate carrier in FeMo cofactor biosynthesis.                                                                                                                                                                                                                                                                                                                                                                           |
| <i>nifY</i>                        | Product: NifY.<br>Possible function: NifY attaches to the FeMo cofactor-deficient, NifB <sup>−</sup> MoFe protein in case of Kp. Might be an intermediate carrier in FeMo cofactor biosynthesis.                                                                                                                                                                                                                                                                                                                                 |
| <i>nifN</i>                        | Product: NifN. Forms $\alpha_2\beta_2$ tetramer ( $M_r \approx 210\,000$ Da) with the <i>nifE</i> gene product (NifN <sub>2</sub> E <sub>2</sub> ). Each tetramer contains two identical redox-active [4Fe–4S] clusters. NifN bears significant sequence identity when compared with the $\beta$ subunit of the MoFe protein.<br>Function: Required for FeMo cofactor biosynthesis. NifN <sub>2</sub> E <sub>2</sub> appears to provide a transient site upon which one or more events related to FeMo cofactor assembly occurs. |
| <i>nifE</i>                        | Product: NifE. Forms $\alpha_2\beta_2$ tetramer ( $M_r \approx 210\,000$ Da) with the <i>nifN</i> gene product (NifN <sub>2</sub> E <sub>2</sub> ). NifE bears significant sequence identity when compared with the $\alpha$ subunit of the MoFe protein.<br>Function: See <i>nifN</i> .                                                                                                                                                                                                                                         |
| <i>nifM<sup>a</sup></i>            | Product: NifM.<br>Function: Required for activation of the Fe protein.                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| <i>nifU<sup>a</sup></i>            | Product: NifU. Provides an in vitro scaffold for the formation of [2Fe–2S] clusters destined for nitrogenase metallocluster assembly.<br>Functions: Complements NifS in the mobilization of Fe and S for metallocluster assembly. Required for the activity of the Fe protein and the MoFe protein.                                                                                                                                                                                                                              |
| <i>nifS<sup>a</sup></i>            | Product: Pyridoxal-dependent cysteine desulfurase.<br>Functions: Complements NifU in the mobilization of Fe and S for metallocluster assembly. Required for the activity of Fe protein and MoFe protein.                                                                                                                                                                                                                                                                                                                         |
| <i>nifW</i>                        | Product: NifW.<br>Function: Required for full activity of the MoFe protein.<br>Possible function: Might be related in coupling Mo and homocitrate.                                                                                                                                                                                                                                                                                                                                                                               |

<sup>a</sup>Also required for the vanadium and iron-only nitrogenases, which are encoded by *vnf* and *anf* genes, respectively.

**Figure 12** Assembly of the molybdenum nitrogenase. Pathways of FeMo cofactor biosynthesis, Fe protein maturation, and MoFe protein assembly are indicated in dotted, dashed, and solid arrows, respectively. The *nif* gene products that are also required for the vanadium and iron-only nitrogenase systems are indicated by \*

FeMo cofactor insertion ('open' conformation) involves at least the combined action of Fe protein, GroEL, MgATP, and possibly  $\gamma$ .<sup>106–108,110,112</sup> Once the FeMo cofactor site is accessible, the FeMo cofactor is inserted,  $\gamma$  dissociates, and the assembly process of the mature nitrogenase is completed.

As mentioned above, a FeMo cofactor-deficient MoFe protein was obtained from a *nifB* deletion strain of *A. vinelandii*, and its X-ray crystal structure has been resolved at 2.3 Å.<sup>43</sup> Like the wild-type *A. vinelandii* MoFe protein (see Section 2.2), this MoFe protein (designated NifB<sup>−</sup> MoFe protein)<sup>43</sup> is an  $\alpha_2\beta_2$  tetramer consisting of a pair of  $\alpha\beta$  dimers that are related by a molecular twofold rotation axis, and each subunit consists of three domains, designated  $\alpha$ I,  $\alpha$ II, and  $\alpha$ III and  $\beta$ I,  $\beta$ II, and  $\beta$ III, respectively. In the dithionite-reduced state, the P cluster of the NifB<sup>−</sup> MoFe protein, like that of its wild-type counterpart, is assigned to the P<sup>N</sup> state and is located between domains  $\alpha$ I and  $\beta$ I. However, the FeMo cofactor of the wild-type MoFe protein, which occupies a cavity formed between domains

of the  $\alpha$  subunit, is not present in the NifB<sup>−</sup> MoFe protein (Figure 13). Accompanying the absence of the FeMo cofactor, domain  $\alpha$ III of the NifB<sup>−</sup> MoFe protein undergoes substantial structural rearrangements, whereas domains  $\alpha$ I and  $\alpha$ II as well as the  $\beta$  subunit of the NifB<sup>−</sup> MoFe protein remain mostly unchanged relative to those of the wild-type MoFe protein. The structural rearrangements of domain  $\alpha$ III in the NifB<sup>−</sup> MoFe protein create a FeMo cofactor insertion funnel, which is not present in its wild-type counterpart. Despite the prevailing negative surface charge of the NifB<sup>−</sup> MoFe protein, there is an evident accumulation of positive surface charge lining the funnel the entire way from the entrance down to the FeMo cofactor binding site.<sup>43</sup> Since the FeMo cofactor is overall negatively charged owing to the dominant contribution of homocitrate,<sup>4</sup> this electrostatic feature of the insertion funnel presumably helps to steer the FeMo cofactor down the funnel into its correct position in the holoprotein. Given the instability of the isolated FeMo cofactor, the biosynthetic pathway likely involves the protein-bound FeMo

**Figure 13** Front-side view of one  $\alpha\beta$  subunit pair of the NifB<sup>−</sup> MoFe protein of *A. vinelandii*, with the  $\alpha$  and  $\beta$  subunits colored in light and dark gray, respectively. The polypeptide chains are shown in ribbon presentation, and the P cluster is shown in space-filling representation. The FeMo cofactor binding site is indicated. PDB entry 1L5H and programs MOLSCRIPT<sup>29</sup> and RASTER3D<sup>30</sup> were used to generate this figure

cofactor instead of the free cofactor. Although the penultimate carrier of the FeMo cofactor preceding its incorporation into the MoFe protein has not been conclusively identified, the rearrangement of the  $\alpha_{III}$  domain might create a potential interaction domain for the docking of the FeMo cofactor donor, in addition to generating the opening for FeMo cofactor insertion.

## 5 ALTERNATIVE NITROGENASES

### 5.1 Vanadium Nitrogenase

#### 5.1.1 General Properties

The vanadium nitrogenase has been isolated from *A. vinelandii* and *A. chroococcum* (Table 1). With the molybdenum in the protein replaced by vanadium, the vanadium nitrogenase resembles its molybdenum counterpart.<sup>5,8,10,16</sup> It has the molybdenum–iron (MoFe) protein equivalent in the vanadium–iron (VFe) protein, as well as the iron (Fe) protein equivalent.

In contrast to the  $\alpha_2\beta_2$  tetrameric MoFe protein, the VFe protein isolated from *A. chroococcum* is an  $\alpha_2\beta_2\delta_2$  hexamer under optimal experimental conditions.<sup>5,16</sup> The VFe protein from *A. vinelandii*, however, shows variable subunit composition.<sup>32</sup> Two species of the *A. vinelandii* VFe protein, that is,  $\alpha\beta_2(\delta)$  and  $\alpha_2\beta_2(\delta)$ , have been characterized<sup>32</sup>

(Table 1). The exact stoichiometry between the  $\alpha$ ,  $\beta$ , and  $\delta$  subunits has not been established in this case, and the suboptimal subunit composition was speculated to be a result of the weak interactions between the subunits.<sup>36</sup> Other than the subunit composition, the VFe proteins from *A. vinelandii* and *A. chroococcum* have similar properties, which is consistent with the sequence homology of their structural genes. The  $\alpha$  and  $\beta$  subunits of the VFe protein, encoded by *vnfD* and *vnfK* genes, respectively, are homologous to the *nifD*-encoded  $\alpha$  and *nifK*-encoded  $\beta$  subunits of the MoFe protein,<sup>8,10</sup> whereas the additional small  $\delta$  subunit of the VFe protein is encoded by *vnfG* (Table 3).<sup>5,8,16,31–36</sup> The VFe protein contains, in preparations with the highest activity, up to 2 vanadium (V) atoms, ~20 iron atoms, and ~20 acid-labile sulfur atoms (Table 1). These metal contents are lower than those typically determined in MoFe protein preparations, which is most likely not significant since comparable values were commonly obtained in earlier studies of the MoFe proteins, but have increased with time.<sup>36</sup> Although no X-ray crystallographic data are currently available for the VFe proteins, EPR, MCD, Mössbauer, EXAFS, and cofactor extrusion studies indicate that the VFe proteins from both *A. vinelandii* and *A. chroococcum* contain redox centers that are respective homologues to the P cluster and FeMo cofactor,<sup>5,8,36</sup> leading to the hypothesis that the structure of the VFe protein resembles that of the MoFe protein apart from the presence of the additional  $\delta$  subunit in the VFe protein. The homologue of the FeMo cofactor in the VFe protein is the designated FeVa cofactor or FeVaco.

The Fe protein of the vanadium nitrogenase, encoded by *vnfH*, shares a high degree of homology with the *nifH*-encoded Fe protein of the molybdenum nitrogenase.<sup>8</sup> Like its counterpart in the molybdenum enzyme, the Fe protein of the vanadium nitrogenase has an  $\alpha_2$  homodimeric composition and contains an [4Fe–4S] cluster.

#### 5.1.2 Catalysis and Assembly

The requirements for vanadium nitrogenase activity are very similar to those of the molybdenum nitrogenase in that both the Fe protein and the VFe protein are essential, MgATP hydrolysis is required, dioxygen needs to be absent, and a reductant like ferredoxin or flavodoxin in vivo or dithionite in vitro is necessary (Figure 1c).<sup>5,8,16</sup> However, there are clear differences in the substrate-reducing profiles of the two enzymes.<sup>5,8,10,16</sup> First, the vanadium nitrogenase fixes N<sub>2</sub> less efficiently than the molybdenum nitrogenase at 30 °C (Table 1). This relationship is reversed at low temperatures. Secondly, in contrast to the molybdenum nitrogenase, hydrazine is a side product of N<sub>2</sub> reduction in the case of the vanadium nitrogenase. Thirdly, the vanadium nitrogenase reduces acetylene, relatively poorly than the molybdenum enzyme, to not only ethylene, which is the only product generated by the molybdenum

enzyme, but also to small amounts of ethane (Tables 1 and 2).

As indicated in Table 3 and Figure 12, some *nif* gene products, for example, NifS, NifU, NifM, NifB, and NifV are also required for the biosynthesis of the vanadium nitrogenase of *A. vinelandii*. However, the expression of the vanadium nitrogenase is regulated by a different activator (i.e. *vnfA*) than the molybdenum enzyme.<sup>8</sup> Molybdenum inhibits the expression of the vanadium nitrogenase. Therefore, in the presence of molybdenum, only the molybdenum nitrogenase is expressed, whereas in the absence of molybdenum, vanadium activates the expression of the vanadium nitrogenase.

In the case of the molybdenum nitrogenase, NifN<sub>2</sub>E<sub>2</sub> is believed to be critical for the biosynthesis of the FeMo cofactor and functions as a transient scaffold on which modifications of the NifB cofactor occur (Section 4.2.1). Since the vanadium nitrogenase contains respective homologues to the *nifN* and *nifE* genes of the molybdenum nitrogenase, namely, *vnfN* and *vnfE*,<sup>8,84</sup> it is possible that *vnfN* and *vnfE* encode a similar transient scaffold protein complex for the biosynthesis of FeVa cofactor. Given that NifB is also required for the assembly of the vanadium nitrogenase, it is likely that the NifB cofactor binds to VnfN<sub>2</sub>E<sub>2</sub> during the biosynthesis of FeVa cofactor in a fashion similar to that when it binds to NifN<sub>2</sub>E<sub>2</sub>. In addition, homocitrate synthesized by NifV might be added to the FeVa cofactor at a similar step in the biosynthesis pathway that is analogous to the FeMo cofactor biosynthesis (see Figure 12). Furthermore, NifS and NifU are most likely important for the mobilization of iron and sulfur and the assembly of Fe/S fragments for the vanadium nitrogenase, and NifM is likely required for the maturation of VnfH.

## 5.2 Iron-only Nitrogenase

### 5.2.1 General Properties

The iron-only nitrogenase has been isolated from *A. vinelandii*, *R. rubrum*, and *R. capsulatus* (Table 1). It is also similar to the molybdenum nitrogenase except that the molybdenum is replaced by iron in the protein.<sup>5,8,10,16</sup> It has the molybdenum–iron (MoFe) protein equivalent in the iron–iron (FeFe) protein and the iron (Fe) protein equivalent.

As shown in Table 1, like the VFe protein, the FeFe protein has an  $\alpha_2\beta_2\delta_2$  hexameric subunit composition under optimal conditions. The  $\alpha$ ,  $\beta$  and  $\delta$  subunits of the FeFe protein are encoded by *anfD*, *anfK*, and *anfG*, respectively. Earlier efforts to purify the FeFe protein suffered from low activities, though progress has been made and recent preparations of the FeFe protein from *R. capsulatus* have activities comparable to that of the VFe protein and do not contain molybdenum or vanadium but high levels of iron (Table 1).

Recent EPR,<sup>35</sup> Mössbauer, and EXAFS<sup>113</sup> studies of the FeFe protein from *R. capsulatus* have provided spectroscopic evidence that the metal clusters of the FeFe protein bear a certain degree of structural homology to those present in the MoFe and VFe proteins. Therefore, it is likely that the FeFe protein contains redox centers that are homologous to the P cluster and FeMo or FeVa cofactor, respectively. The FeMo or FeVa cofactor homologue in the FeFe protein is termed FeFe cofactor or FeFeco.

The *anfH*-encoded Fe protein of the iron-only nitrogenase is very homologous to the *nifH*-encoded Fe protein of the molybdenum nitrogenase and the *vnfH*-encoded Fe protein of the vanadium nitrogenase.<sup>8</sup> This Fe protein also has an  $\alpha_2$  homodimeric composition and contains a [4Fe–4S] cluster.

### 5.2.2 Catalysis and Assembly

The requirements for the substrate-reduction activity of the iron-only nitrogenase are similar to those of the vanadium nitrogenases (Figure 1c).<sup>8,10</sup> The expression of the iron-only nitrogenase is only activated in the absence of both molybdenum and vanadium and regulated by a different activator (i.e. *anfA*) than the molybdenum or vanadium enzyme.<sup>8</sup> In contrast to the vanadium nitrogenase, the iron-only nitrogenase does not contain homologues to the *nifN* and *nifE* genes. Therefore, the biosynthesis of FeFe cofactor relies on not only the *nif* gene products (i.e. NifS, NifU, NifM, NifB, and NifV), but also on the *vnf* gene products (i.e. VnfN and VnfE). The VnfN<sub>2</sub>E<sub>2</sub> complex might act as a transient scaffold for the biosynthesis of both the FeVa cofactor and the FeFe cofactor.<sup>8</sup>

## 5.3 *Streptomyces thermoautotrophicus* Nitrogenase

*S. thermoautotrophicus* was isolated from the covering soil of a burning charcoal pile.<sup>14,15</sup> The bacterium uses gases as sources of energy, carbon, and nitrogen (hence designated gasotrophy) and is able to fix N<sub>2</sub> with CO or H<sub>2</sub> plus CO<sub>2</sub> as growth substrate under aerobic conditions.<sup>14</sup> N<sub>2</sub> fixation by *S. thermoautotrophicus* exhibits features that are not present in other nitrogen-fixing bacteria. N<sub>2</sub> reduction in this case is coupled with the oxidation of carbon monoxide (CO) by a molybdenum-containing CO dehydrogenase (designated ST3) that transfers the electrons derived from CO oxidation to O<sub>2</sub>, thereby producing superoxide anion radicals (O<sub>2</sub><sup>•−</sup>). A manganese-containing superoxide oxidoreductase (designated ST2) reoxidizes O<sub>2</sub><sup>•−</sup> to O<sub>2</sub> and transfers the electrons to a MoFeS-dinitrogenase (designated ST1), where the reduction of N<sub>2</sub> occurs. Among the most striking properties of the *S. thermoautotrophicus* nitrogenase system are the dependence of the enzyme on O<sub>2</sub> and O<sub>2</sub><sup>•−</sup>, the complete insensitivity of all components involved toward O<sub>2</sub> and H<sub>2</sub>O<sub>2</sub>, the inability of the enzyme

to reduce ethyne or ethene, and a low MgATP requirement for enzymatic activities. In addition, the subunit structure of the *S. thermoautotrophicus* nitrogenase components and the polypeptides involved seem to be dissimilar from the known nitrogenases.<sup>15</sup>

## 6 SUMMARY

Nitrogenases are a class of metalloenzymes that catalyze biological N<sub>2</sub> fixation, the overall reaction of which is usually depicted as:  $\text{N}_2 + 8\text{H}^+ + 16\text{MgATP} + 8\text{e}^- \rightarrow 2\text{NH}_3 + \text{H}_2 + 16\text{MgADP} + 16\text{P}_i$ . Four classes of nitrogenases, that is, the molybdenum nitrogenase, the vanadium nitrogenase, the iron-only nitrogenase, and the *S. thermoautotrophicus* nitrogenase, have been described. The first three classes of nitrogenases are very similar except for the heterometal atom in the active site of the metal cluster (molybdenum, vanadium, or iron), whereas the fourth is superoxide-dependent and apparently different from the other nitrogenases.

The best-characterized molybdenum nitrogenase comprises two metallosulfur proteins, that is, the molybdenum-iron (MoFe) protein and the iron (Fe) protein, both of which are essential for the enzymatic activity. The Fe protein is an  $\alpha_2$  homodimer (encoded by *nifH*) of  $M_r \sim 60$  kDa. The two subunits are bridged by a [4Fe–4S] cluster and each has a MgATP binding site. The MoFe protein is an  $\alpha_2\beta_2$  tetramer (encoded by *nifD* and *nifK*) of  $M_r \sim 220$  kDa. It contains the [8Fe–7S] cluster (P cluster) that is bridged between each  $\alpha\beta$  subunit pair and the [Mo–7Fe–9S–homocitrate] cluster (FeMo cofactor or FeMoco) that is located within each  $\alpha$  subunit.

The catalysis of molybdenum nitrogenase occurs in a series of steps. First, the reduced Fe protein binds two molecules of MgATP and undergoes a conformational change before forming a complex with the MoFe protein. Then, coupled with the hydrolysis of two MgATP molecules to 2MgADP and 2P<sub>i</sub>, one electron is transferred from the Fe protein to the MoFe protein within the complex. This is followed by complex dissociation, re-reduction of the oxidized Fe protein, and the dissociation of MgADP, which allows the enzyme to start the next cycle of electron transfer. Once a sufficient amount of electrons is accumulated in the MoFe protein, reduction of the bound substrate takes place.

The assembly of the molybdenum nitrogenase Fe protein involves the *nifH* gene and at least the *nifS*, *nifU*, and *nifM* gene products that are implicated in the [4Fe–4S] cluster assembly, while the assembly of MoFe protein requires at least 15 *nif* gene products and involves the biosynthesis of FeMo cofactor and FeMo cofactor-deficient MoFe protein in separate pathways and the insertion of FeMo cofactor into the MoFe protein.

## 1 INTRODUCTION

In the early 1890s, Lord Rayleigh discovered that nitrogen obtained by removal of the gases  $O_2$ ,  $CO_2$ ,  $H_2O$  from an air sample was denser than nitrogen obtained by chemical procedures. Among other theories for this discrepancy was the idea that some heavier unknown gas was present in the air. In 1894, Lord Rayleigh and William Ramsay discovered that this unknown gas was a new element.<sup>1</sup> Because the gas was shown to be chemically inert, they named it argon, from Greek, *argon*, meaning inactive. The other members of the noble gas (Ng) series were discovered and isolated in the subsequent years up to 1900 by William Ramsay and his assistant Morris Travers. They used a new experimental technique, low-temperature distillation.

The element helium, from Greek *helios*, the sun, had already been noted in the Sun's spectrum in 1868, but was not isolated as a terrestrial element until 1895, when Ramsay obtained it by heating the mineral uraninite in which the helium was physically trapped. With an improved technique of liquid air distillation, Ramsay and Travers isolated neon (Greek, *neos*, new), krypton (Greek, *kryptos*, hidden), and xenon (Greek,

*xenon*, stranger). An excellent account of the discovery of the noble gases and the early controversy regarding the discovery of argon is given by Travers.<sup>2</sup>

The last of the family of the noble gases was found in 1900 by Owens and Rutherford. This was radon-220, a product of the *Radioactive Decay* of thorium. Also in the same year, radon-222, which is a product of the radioactive decay of radium, was discovered by Dorn.

This article will cover the general chemistry of some of the more common noble gas species, including fluorides, oxides, transition metal salts, and derivatives of carbon and nitrogen.

## 2 THE NOBLE GAS ELEMENTS

Helium is the second most abundant element in the universe. In the Earth, it is continuously formed by radioactive decay, mostly of uranium and thorium. Its present concentration in the atmosphere is probably the equilibrium concentration between the amount being released from the Earth's crust and the amount of helium escaping from the atmosphere into space. The atmosphere represents the major source for neon, argon, krypton, and xenon. They are produced as by-products during fractional distillation of liquid air. Radon is obtained from the radioactive decay of radium.

The noble gases have closed-shell electronic structures ( $1s^2$  for helium and  $ns^2np^6$  for the other noble gases) (*see Electronic Structure of Main-group Compounds*) and are extremely stable, as shown by the high ionization energies, especially of the lighter members: He, 24.58; Ne, 21.56; Ar, 15.76; Kr, 14.00; Xe, 12.13; Rn, 10.75 eV. They are all colorless, odorless, tasteless, low-boiling, monoatomic gases whose physical properties vary systematically with atomic number.<sup>3</sup> The boiling point of helium is the lowest of any known substance. The weak forces between noble gas atoms are proportional to the *Polarizability* element and increase with the increasing size of the electron clouds.

The ability of these gases to form true chemical compounds with other atoms is limited to the heavier members of the group, krypton, xenon, and radon, where the first ionization energies are reduced to a level comparable with other chemically active elements. Theoretical studies, however, have indicated that it may be possible to isolate helium derivatives, such as  $MeBeHe$ .<sup>4</sup> Many of the compounds are prepared at low temperature and characterized through spectroscopic techniques. More recently, multinuclear NMR has emerged as an extremely useful characterization technique.<sup>5</sup>

## 3 WEAKLY BONDED SPECIES OF NOBLE GASES

The species known before 1962 that contained noble gases combined with other elements and molecules were

cationic species, observed only in the gas phase, or inclusion compounds. The latter involve noble gas atoms held in host crystal lattices, with only weak London exchange interactions helping to fix the gases in the lattice cage.

Emission spectra from discharge tubes or from mass spectrometric studies containing a single gas or mixtures of pure noble gases give evidence for the presence of diatomic molecules. Usually, it is not clear if these are neutral molecules or ions. Ions are more likely to exist because chemical bond formation seems more likely when the closed-shell arrangement is destroyed by removal of an electron. There is also spectroscopic evidence for diatomic molecules between noble gas atoms and other atoms (e.g. H, O, N, Hg) or molecules (e.g. CO<sub>2</sub>, N<sub>2</sub>, SF<sub>6</sub>, etc.). All these species have exceedingly short lifetimes.

Inclusion compounds, or clathrates, are known where the noble gas is present within a crystalline framework of water (general ideal formula 8Ng·46H<sub>2</sub>O) or hydroquinone (Ng·3C<sub>6</sub>H<sub>4</sub>(OH)<sub>2</sub>). There are no chemical bonds holding the guest atoms or molecules to the host molecules. Because it is difficult to define exactly what is and what is not a chemical bond, it is better to compare the energies involved.<sup>6</sup> The energies with which noble gas atoms are bound in clathrates are 10 times higher than the van der Waals energies between the noble gas atoms probably owing to the permanent dipoles possessed by the host molecules. By comparison, the energies in common chemical bonds are 10 times higher than bonding energies in clathrates. There are extensive reviews of weakly bound species of noble gases by Holloway<sup>7</sup> and Bartlett and Sladky.<sup>8</sup>

## 4 THE PREPARATION OF THE FIRST TRUE CHEMICAL COMPOUND OF A NOBLE GAS

After argon was isolated as the first member of the noble gas group in 1894 by Rayleigh and Ramsay, they tried various chemical reagents to form compounds of the new element, but without success. Ramsay also sent a 100-mL sample of the gas to his friend Moissan, the discoverer of fluorine, so that he could attempt to prepare a fluoride. His unsuccessful experiment was considered the ultimate test for the chemical inertness of argon. Unfortunately, some years later, the electronic theory of valence reinforced the notion of the chemical inertness of the noble gases. The noble gas valence-electron configuration was defined as the configuration to which other elements tend in their chemical bonding.

In 1933, besides some theoretical speculations that noble gas compounds should exist, some new reports of unsuccessful experiments to prepare noble gas compounds were published. The most promising experiment was carried out by Yost and Kaye<sup>9</sup> at the suggestion of Pauling, who was convinced that at least the heavier noble gases, for example, xenon, should react with the most electronegative elements, for example,

fluorine (*see Fluorine: Inorganic Chemistry*). The failure of Yost and Kaye was really very unfortunate, since a similar experiment, carried out 32 years later, using sunlight in place of their electrical discharge, was successful.

Bartlett and Lohmann proved that an oxyfluoride of platinum, made by fluorination in the presence of oxygen, was the salt O<sub>2</sub><sup>+</sup>PtF<sub>6</sub><sup>-</sup>. This indicated that PtF<sub>6</sub> was an oxidizer of unexpected power. Bartlett immediately noted that the ionization potential of the xenon atom is almost identical to that of the oxygen molecule (*I*(O<sub>2</sub>) = 12.2 eV, *I*(Xe) = 12.13 eV). He tried the reaction of xenon gas with PtF<sub>6</sub> vapors. Yellow–orange xenon fluoroplatinate(V) was obtained.<sup>10</sup> This and the subsequent studies at Argonne National Laboratory, where PtF<sub>6</sub> had first been prepared in 1957, started a new era of inorganic chemistry. Interest was so wide that a special meeting on noble gas compounds was organized at Argonne eight months after the first preparation of the true xenon compound.<sup>11</sup> Since then, many books and reviews treating the developments in noble gas chemistry have been published.<sup>8,12–16</sup>

## 5 THE CHEMISTRY OF XENON

### 5.1 Xenon Fluorides

Three binary fluorides of xenon are known: XeF<sub>2</sub>, XeF<sub>4</sub>, and XeF<sub>6</sub>. XeF<sub>8</sub> is not known (*see Fluorides: Solid-state Chemistry*). The fluorides are readily prepared from the elements and are thermodynamically stable. Full characterization data is available for these compounds, including gas-phase <sup>129</sup>Xe and <sup>19</sup>F NMR data.<sup>17</sup> The commercial availability of XeF<sub>2</sub> has greatly increased the study and use of this reagent.<sup>18</sup>

#### 5.1.1 Xenon Difluoride

Xenon difluoride was prepared for the first time from a xenon–fluorine gas mixture using an electric discharge.<sup>19</sup> Other kinds of energy, such as heat, UV light, sunlight, high-intensity  $\gamma$ -radiation, irradiation by electrons from a van de Graaff accelerator, irradiation by 10 MeV protons and so on, are also effective. A convenient preparation using very simple apparatus, and affording a pure product, is the exposure of a xenon–fluorine gas mixture to sunlight. Very pure XeF<sub>2</sub> in greater quantities (up to 1 kg) can be best prepared by UV irradiation (*see Photosynthesis*) of a gaseous xenon–fluorine mixture in the mole ratio 1:2, with addition of about 1 mol% of HF in the fluorine as a catalyst. The thermal reaction between xenon and fluorine to form xenon difluoride is heterogeneous and takes place on the prefluorinated walls of the reaction vessel and/or the surface of an added fluoride, such as NiF<sub>2</sub>. In the presence of NiF<sub>2</sub>, it is possible to synthesize even XeF<sub>6</sub> at

393 K, starting with the gaseous mixture  $\text{Xe}:\text{F}_2 = 1:5$ . Xenon difluoride is colorless as solid, liquid, or gas. The vapor pressure of the solid at 298 K is  $6.0 \times 10^2$  Pa, and therefore at room temperature large crystals are usually formed. The  $\Delta H_f$  (solid) is  $-163 \text{ kJ mol}^{-1}$ .

In crystalline  $\text{XeF}_2$ , the linear molecules are aligned parallel in a body-centered tetragonal array (Figure 1). Each xenon atom has two bound fluorine atoms at  $2.00 \text{ \AA}$  and eight fluorine atoms from fluorine ligands of the eight nearest  $\text{XeF}_2$  neighbors at  $3.42 \text{ \AA}$ . It is evident that there are strong interactions between  $\text{XeF}_2$  molecules. This structural arrangement is compatible with the high enthalpy of sublimation of  $\text{XeF}_2$  ( $55.7 \text{ kJ mol}^{-1}$ ) and the assumed charge distribution in each molecule ( $^{-0.5}\text{F}-\text{Xe}^{+1}-\text{F}^{-0.5}$ ). It is further evident from the packing arrangement that the equatorial region of each  $\text{XeF}_2$  molecule is avoided by fluorine ligands of neighboring molecules because the nonbonding valence electrons of the xenon atom effectively shield the positive charge on the xenon.

Xenon difluoride dissolves in the halogen fluorides  $\text{BrF}_3$ ,  $\text{BrF}_5$ , and  $\text{IF}_5$  and in AHF (anhydrous hydrogen fluoride) as monomolecular species geometrically similar to the gas-phase species.  $\text{XeF}_2$  sometimes forms complexes with the solvents (e.g.  $\text{BrF}_3$  and  $\text{IF}_5$ ).  $\text{XeF}_2$  is also soluble in MeCN and other organic solvents.

$\text{XeF}_2$  is potentially a strong oxidizer, but is frequently unreactive for kinetic reasons. Its stability in aqueous solution is an example of this kinetic inertness.  $\text{XeF}_2$  dissolves in water ( $\approx 25 \text{ g L}^{-1}$  at 273 K) with only slight decomposition.  $\text{XeF}_2$

may be recovered by extraction with  $\text{CCl}_4$  or by fractional distillation. The equilibrium constant for equation (1) has been estimated to be about  $10^{40}$ . This explains the observation that the fluorination of uranium and zirconium oxides by  $\text{XeF}_2$  is initiated by the addition of water to the reaction mixture.<sup>20</sup>  $\text{XeF}_2$  is, generally, a very good fluorinating agent for a wide range of substrates.<sup>21</sup>

Neutral and acid aqueous solutions of  $\text{XeF}_2$  decompose rather slowly (half-life being  $\approx 7 \text{ h}$  at 273 K), while the decomposition in basic solution is fast, the base catalytic effect being roughly in the order of the base strength.  $\text{XeF}_2$  is stable in dried propylene carbonate.<sup>22</sup>

### 5.1.2 Xenon Tetrafluoride

Xenon tetrafluoride was the first noble gas binary fluoride to be synthesized. It was prepared by heating a gaseous mixture of xenon and fluorine in the mole ratio 1:5 at a total pressure of 0.6 MPa at 673 K in a closed nickel can.<sup>23</sup> These conditions are close to the optimum for  $\text{XeF}_4$  preparation.<sup>24</sup> Low temperatures and high-fluorine pressures favor  $\text{XeF}_6$  formation, while low fluorine pressures and high temperatures favor  $\text{XeF}_2$  formation. If high purity  $\text{XeF}_4$  is desired, it is necessary to purify it by chemical methods because it is nearly impossible to separate xenon difluoride from the tetrafluoride by physical means (the two have similar vapor pressures and also form a 1:1 adduct). A general chemical purification method that can be used for any mixture of xenon fluorides exploits the inferior fluoride ion donor ability of  $\text{XeF}_4$  compared to  $\text{XeF}_2$  or  $\text{XeF}_6$  (equation 2).<sup>25</sup>

Other preparative methods include the photochemical reaction between xenon and excess of fluorine in the presence of  $\text{NiF}_2$  as catalyst, thermal decomposition of  $\text{XeF}_6$  in the presence of NaF (this method is also convenient for the preparation of pure fluorine) and the pyrolysis of some  $\text{XeF}^+$  salts such as  $\text{XeF}^+\text{PtF}_6^-$  or  $\text{XeF}^+\text{Pd}_2\text{F}_9^-$  at 423 K (equations 3 and 4).

$\text{XeF}_4$  is colorless as crystals, liquid, or vapor. The vapor pressure of the solid at 298 K is  $3.4 \times 10^2$  Pa and the  $\Delta H_f$  is  $-266 \text{ kJ mol}^{-1}$ . Vibrational spectroscopic and electron diffraction data have proven that the  $\text{XeF}_4(\text{g})$  molecule is

Figure 1 Unit cell of xenon difluoride

**Figure 2** Molecular packing in  $\text{XeF}_4$  as seen in projection down the  $b$  axis. The numbers on some of the atoms are  $b$  coordinates ( $\times 100$ )

square-planar ( $D_{4h}$ ) with a Xe–F bond length of 1.94 Å (see *Diffraction Methods in Inorganic Chemistry*). The size and the shape of  $\text{XeF}_4$  in the crystal is not significantly different from the gas-phase molecule (see Figure 2). The Xe–F bond length in the solid is 1.953 Å and the F–Xe–F angle is  $90.0^\circ$ . The enthalpy of sublimation of  $\text{XeF}_4$  ( $61 \text{ kJ mol}^{-1}$ ) indicates strong electrostatic interactions between  $\text{XeF}_4$  molecules, as in the case of  $\text{XeF}_2$ .

$\text{XeF}_4$  can be kept in thoroughly dried glass or quartz and can be stored indefinitely in Kel-F (polyfluorotrichloroethylene), nickel, or monel containers.  $\text{XeF}_4$  hydrolyzes very rapidly, with one-third of the xenon remaining in the solution as the trioxide (equation 5).

The low bond energy of  $\text{XeF}_4$  causes it to be a strong oxidative fluorinator (comparable with  $\text{BrF}_3$ ), but it has high-kinetic inertness like  $\text{XeF}_2$ .

### 5.1.3 Xenon Hexafluoride

The first synthesis of  $\text{XeF}_6$  was also reported in 1962.<sup>26</sup> All syntheses are best carried out in nickel or monel reaction vessels. From the equilibrium constants for the formation of xenon fluorides,<sup>24</sup> it is evident that an excess of fluorine is necessary to minimize the formation of  $\text{XeF}_4$ . In addition, the reaction temperature should be as low as possible, yet consistent with a reasonable reaction rate. In the presence of  $\text{NiF}_2$  as catalyst the activation energy for the xenon–fluorine reaction is lowered and the reaction proceeds rapidly at 393 K, in contrast to 523 K without catalyst.

$\text{XeF}_6$  may be purified from other xenon fluorides and  $\text{XeOF}_4$  by its complexation with sodium fluoride at 323 K. Impurities ( $\text{XeOF}_4$ ,  $\text{XeF}_2$ ,  $\text{XeF}_4$ ) may be removed under

vacuum at 323 K, the  $\text{Na}_2\text{XeF}_8$  complex being stable at that temperature.  $\text{XeF}_6$  is recovered by decomposing the complex at 398 K. Solid  $\text{XeF}_6$  is colorless below the melting point, while the liquid and vapor are yellow–green.  $\text{XeF}_6$  is much more volatile than  $\text{XeF}_2$  or  $\text{XeF}_4$ , although much less so than other hexafluorides. Its  $\Delta H_f$  is  $-338 \text{ kJ mol}^{-1}$ .

The crystal structure of solid  $\text{XeF}_6$  is complex. The solid assumes at least four distinct crystalline polymorphic forms (see *Polymorph*). The existence of three modifications was shown by heat capacity measurements.<sup>27</sup> These polymorphic phases were designated I, II, and III in order of decreasing temperature, with transitions at 291.8 K and 253.8 K. The phase IV is a cubic phase that exists from the melting point of  $\text{XeF}_6$  to at least 93 K. Phase I is a high-temperature monoclinic modification, phase II is the orthorhombic form, and phase III is a low-temperature monoclinic form. The phases I, II, and III all contain tetrameric rings that approximate to  $\text{F}^-$ -bridged  $\text{XeF}_5^+$  clusters. Transformations between these three phases occur relatively easily, since all contain only tetramers. Solid–solid transformations seem to occur only when both phases contain the same structural units. Solid–solid transformations are not observed between these tetramer-based phases and the cubic phase, which contains both tetramers and hexamers. The crystal structure of the cubic modification (phase IV)<sup>28</sup> is shown in Figure 3. The hexameric clusters, like the tetramers, can also be viewed as  $\text{F}^-$ -bridged clusters of  $\text{XeF}_5^+$  species. Clearly, this phase cannot transform to the tetramer-based forms without breakup of the hexameric units, which must require considerable reorganization energy.

A comparison of the density of liquid  $\text{XeF}_6$  with the densities of all the other hexafluorides shows that its density is unexpectedly high. This is linked with the association of the molecules in the liquid phase and may well involve aggregations similar to those observed in the crystal phases. The unusually large heat capacity of the liquid is in accord with this. Near the melting point the heat capacity of the liquid is almost twice as great as that of the solid. This places  $\text{XeF}_6$  not only in a unique position among the other hexafluorides, but also among all other liquids in general. The entropy of vaporization of  $\text{XeF}_6$  at its boiling point has the extraordinarily high value of  $136.9 \text{ J K}^{-1} \text{ mol}^{-1}$ . This seems to be the highest entropy of vaporization observed for any known liquid. The association of molecules in the liquid phase must be caused by intermolecular forces beyond those of the van der Waals type. Strongly interacting  $\text{XeF}_5^+$  and  $\text{F}^-$  species in tight clusters may be the cause. The gas-phase  $\text{XeF}_6$  molecule has no dipole moment, but the autoionization observed in the solid state provides for the required strong association.

$\text{XeF}_6$  is a much more powerful oxidizer and fluorinator than the lower xenon fluorides. It also has lower kinetic stability than  $\text{XeF}_2$  and  $\text{XeF}_4$ . Thus  $\text{XeF}_6$  cannot be stored in glass or quartz, but reacts with them by exchanging fluorine for oxygen to yield initially  $\text{XeOF}_4$ , subsequently  $\text{XeO}_2\text{F}_2$ , and finally xenon trioxide (see Sections 5.2.1 and 9).

**Figure 3** (a) Tetramer of  $\text{XeF}_5^+\text{F}^-$ , (b) hexamer of  $\text{XeF}_5^+\text{F}^-$ . Xenon atoms are indicated by small circles and bridging fluoride ions by large circles;  $\text{XeF}_5^+$  ions are drawn in skeletal form

## 5.2 Xenon Oxides

Among xenon oxides only  $\text{XeO}_3$  and  $\text{XeO}_4$  have been definitively isolated and characterized.  $\text{XeO}$  is known, as a gas-phase species, to be bound with respect to a  $^1\text{D}(0)$  atom but not with respect to ground-state  $^3\text{P}(0)$ . There is no evidence for a condensed phase  $\text{XeO}$  species. Recently, however, the unique radical,  $\text{HXeO}$ , has been isolated by UV photolysis of either  $\text{H}_2\text{O}/\text{Xe}$  or  $\text{N}_2\text{O}/\text{HBr}/\text{Xe}$  solid mixtures as 7 K. The compound was characterized by IR and its intrinsic stability supported by ab initio calculations.<sup>29</sup>

### 5.2.1 Xenon Trioxide

$\text{XeO}_3$  may be prepared by controlled hydrolysis of  $\text{XeF}_6$  at low temperature (equation 6).<sup>30</sup> It can also be derived from  $\text{XeF}_4$  as already described. The best hydrolysis is performed in the presence of sufficient magnesium oxide ( $\text{MgO}$ ) to rapidly neutralize all the hydrogen fluoride ( $\text{HF}$ ) produced. Aqueous  $\text{XeO}_3$  solutions are indefinitely stable if reducing impurities and light are excluded. If the solution is evaporated to dryness the solid oxide may detonate.

$\text{XeO}_3$  is a colorless, hygroscopic, detonatable solid with a low vapor pressure at room temperature. Its  $\Delta H_{\text{sub}}$  is 126 (42)  $\text{kJ mol}^{-1}$  and  $\Delta H_{\text{f}}$  is 402  $\text{kJ mol}^{-1}$ .

### 5.2.2 Xenon Tetroxide

$\text{XeO}_4$  was first prepared by the reaction of concentrated sulfuric acid with xenates(VIII) at room temperature or lower.<sup>31</sup> When the reaction is carried out slowly, about one-third of the xenon is converted to  $\text{XeO}_4$ . The tetroxide is purified by vacuum sublimation.  $\text{XeO}_4$  is a pale yellow solid that, at 273 K, has a vapor pressure of about  $33 \times 10^2$  Pa,

while at 195 K its volatility is still high enough for mass spectrometric detection. Usually, decomposition to xenon and oxygen occurs before the sample reaches 273 K. The decomposition is often violent in accord with the enthalpy of formation of  $\text{XeO}_4$  (642  $\text{kJ mol}^{-1}$ ).  $\text{XeO}_4$  is an oxidizing agent of great power. Its structure has been investigated in the gas phase by electron diffraction and shown to be tetrahedral with  $\text{Xe}-\text{O} = 1.74 \text{ \AA}$ .

## 5.3 Xenon Oxyfluorides

All possible xenon(IV) and xenon(VI) oxyfluorides are known. Among the xenon(VIII) oxyfluorides, only  $\text{XeOF}_6$  is not yet isolated.

### 5.3.1 Xenon Oxide Difluoride

$\text{XeOF}_2$  has been prepared in the reaction of  $\text{XeF}_4$  with water in  $\text{HF}$  solvent at 210 K.<sup>32</sup>  $\text{XeOF}_2$  presumably decomposes slowly even at 210 K to yield  $\text{XeF}_2$  and oxygen. After the reaction is completed, the product is washed with  $\text{HF}$  at 195 K to remove traces of unreacted water and  $\text{XeF}_2$ .  $\text{XeOF}_2$  is a light-yellow solid that decomposes explosively at ca. 273 K. On slow warming from 210 to 273 K over a period of 20 h,  $\text{XeOF}_2$  decomposes to  $\text{XeF}_2$  and  $\text{XeO}_2\text{F}_2$ . The solid  $\text{XeOF}_2$  is characterized by its Raman spectrum (in  $\text{cm}^{-1}$ ) (relative intensities in parentheses): 732 (8), 496 (100), 285 (4), 186 (8), 197 (1).

### 5.3.2 Xenon Oxide Tetrafluoride

$\text{XeOF}_4$  was first detected as an impurity by mass spectrometry among the xenon fluorides prepared by thermal methods. It was obtained in macroscopic quantities by the partial hydrolysis of xenon hexafluoride (equation 7).<sup>33</sup> Unreacted  $\text{XeF}_6$  and  $\text{HF}$  formed in the reaction are removed

by treatment with NaF.

$\text{XeOF}_4$  is known from NMR, vibrational, and *Microwave Spectroscopy* to be a square-based pyramid with an oxygen ligand at the apex ( $C_{4v}$ ). The microwave data show the xenon and four fluorine atoms to be nearly in the same plane. The Xe–F bond length (1.903 Å) is very similar to that found for  $\text{XeF}_6$  (1.890 Å). The Xe–O bond length (1.706 Å) is shorter than in  $\text{XeO}_3$  (1.76 Å) or  $\text{XeO}_4$  (1.74 Å). The observed geometry is consistent with location of the nonbonding electron pair on the fourfold molecular axis trans to the oxygen atom.

$\text{XeOF}_4$  is colorless as solid, liquid, and gas. It has a low-melting point (226.95 K) and is quite volatile ( $11 \times 10^2$  Pa at 273 K). The liquid is nonassociated and the low-electrical conductivity of the pure liquid indicates that autoionization is not significant. The liquid has, at 297 K, a dielectric constant of 24.6 and dissolves alkali fluorides with considerable enhancement of its electrical conductivity.  $\text{XeOF}_4$  is the most stable molecular compound containing a Xe–O bond. It is thermally stable to nearly 573 K, where it starts to decompose slowly to  $\text{XeF}_4$  and oxygen.

### 5.3.3 Xenon Dioxide Difluoride

$\text{XeO}_2\text{F}_2$  was observed in the early mass spectra of xenon fluorides and can be obtained by hydrolysis of  $\text{XeF}_6$ . The best method for its preparation in macroscopic quantities is by the reaction of  $\text{XeO}_3$  and  $\text{XeOF}_4$ .<sup>34</sup> The  $\text{XeOF}_4$  and  $\text{XeF}_2$  impurities may be removed by fractional distillation. Xenon dioxide difluoride forms colorless crystals at room temperature, which have a vapor pressure between that of  $\text{XeO}_3$  and  $\text{XeOF}_4$  and melts at 303.95 K to give a colorless liquid. It can decompose to  $\text{XeF}_2$  and  $\text{O}_2$ .

### 5.3.4 Xenon Dioxide Tetrafluoride

$\text{XeO}_2\text{F}_4$  was made by the reaction of  $\text{XeO}_3\text{F}_2$  (see Section 5.3.5) and  $\text{XeF}_6$  in  $\text{XeOF}_4$  as solvent.<sup>35</sup> It was identified by *Mass Spectrometry*.  $\text{XeO}_2\text{F}_4$  is the most volatile of all known xenon compounds and may therefore possess the symmetrical, nonpolar,  $D_{4h}$  symmetry.

### 5.3.5 Xenon Trioxide Difluoride

$\text{XeO}_3\text{F}_2$  was the first oxyfluoride of octavalent xenon to be prepared. It was made by reaction of  $\text{XeF}_6$  with sodium perxenate solid at room temperature.<sup>36</sup>  $\text{XeO}_3\text{F}_2$  is, like  $\text{XeO}_4$ , sufficiently volatile to distil at 195 K. The much greater volatility of  $\text{XeO}_3\text{F}_2$  as compared to  $\text{XeO}_2\text{F}_2$  indicates that the molecule of  $\text{XeO}_3\text{F}_2$  is more symmetrical and probably nonpolar ( $D_{3h}$ ).

$\text{XeO}_3\text{F}_2$  can be prepared in much better yield by the reaction of  $\text{XeF}_6$  with  $\text{XeO}_4$ . Because  $\text{XeO}_3\text{F}_2$  is rapidly destroyed by  $\text{XeF}_6$  with formation of  $\text{XeOF}_4$ , special care must be taken to remove  $\text{XeO}_3\text{F}_2$  (under vacuum) from the reaction vessel at 195 K immediately after all  $\text{XeO}_4$  has been consumed. Structural information has been derived only from vibrational spectroscopy. On this basis, it has been concluded that the molecule  $\text{XeO}_3\text{F}_2$  has the symmetry  $D_{3h}$ . The melting point of  $\text{XeO}_3\text{F}_2$  is  $219.05 \pm 0.5$  K. The vapor pressure of  $\text{XeO}_3\text{F}_2$  as a function of temperature is (in  $10^2$  Pa) 5 at 222.75 K, 7 at 222.35 K, 16 at 236.25 K, 13 at 236.35 K, 29 at 243.85 K, and 32 at 245.15 K.<sup>37</sup> Its heat of vaporization is  $33.0 \pm 3.0$  kJ mol<sup>−1</sup>. The extrapolated boiling point is 313 K.

## 5.4 The Dixenon Cation

Green  $\text{Xe}_2^+$  is formed either by oxidation of gaseous xenon, for example, with  $\text{O}_2^+\text{Sb}_2\text{F}_{11}^-$  salt, or by reduction of  $\text{XeF}^+$  salt with water or other reducing agents.<sup>38</sup>  $\text{Xe}_2^+$  was also identified by the resemblance of its spectrum to the spectrum of the isoelectronic  $\text{I}_2^-$  anion. The  $\text{Xe}_2^+$  cation has a Raman band at 123 cm<sup>−1</sup>.

## 5.5 Xenon(II) Compounds

$\text{XeF}_2$  forms many compounds with binary fluorides, oxide tetrafluorides, and some anhydrous acids. Strong fluoride ion acceptors, for example, such as  $\text{AsF}_5$  and  $\text{SbF}_5$ , can withdraw a fluoride ion from  $\text{XeF}_2$  forming  $\text{XeF}^+$  species<sup>38,39</sup> or, in the case of excess  $\text{XeF}_2$ , also  $\text{Xe}_2\text{F}_3^+$  species. The increase in the Xe–F bond energy in the cation formation (133.9 kJ mol<sup>−1</sup> in  $\text{XeF}_2$ , 195.9 kJ mol<sup>−1</sup> in the cation) contributes to the fluoride ion donor ability of the difluoride. A study focusing on the Lewis acid reactivity of  $\text{XeF}^+$  with various bases in the gas phase determined the bond dissociation enthalpy to be 188 kJ mol<sup>−1</sup>.<sup>39</sup> Xenon difluoride also forms molecular adducts in which the negatively charged F ligands of  $\text{XeF}_2$  are attracted by the positive center of the partner molecule of the adduct.

Xenon(II) compounds can be prepared by fusing stoichiometric amounts of the component fluorides in an atmosphere of a dry inert gas or by dissolving them in a nonoxidizing or reducing solvent. One component can also be used in excess and removed by vacuum distillation to constant weight. Some reactions between binary fluorides in lower oxidation states and  $\text{XeF}_2$  have also been carried out in a melt of  $\text{XeF}_2$ . Under these conditions, the oxidizing as well as the fluorobasic properties of  $\text{XeF}_2$  are revealed, and  $\text{Xe}^{\text{II}}$  complexes of higher oxidation state fluorides are formed.

### 5.5.1 Compounds with Hexafluorides

In the system  $\text{XeF}_2\text{--MF}_6$ , only the adducts  $\text{XeF}_2\text{MoF}_6$ ,  $\text{XeF}_2\text{WF}_6$ , and  $\text{XeF}_2\text{UF}_6$  have been claimed. The existence

of these adducts was established only from the melting point–composition diagrams. They are not stable at room temperature and they decompose readily into their component compounds.

### 5.5.2 Compounds with Pentafluorides

This type of xenon(II) compound is the most common. With pentafluorides,  $\text{XeF}_2$  forms three types of compounds:  $2\text{XeF}_2 \cdot \text{MF}_5$ ,  $\text{XeF}_2 \cdot \text{MF}_5$ , and  $\text{XeF}_2 \cdot 2\text{MF}_5$ . It is also possible that compositions richer or poorer in  $\text{XeF}_2$  content exist. Both saltlike and fluorine-bridged formulations were suggested to explain the bonding in these compounds. The degree of ionic character in the compounds varies depending on the Lewis acid properties of the pentafluorides involved (*see Lewis Acids & Bases*). The stronger the Lewis acid, the more ionic the compound.  $\text{XeF}^+\text{Sb}_2\text{F}_{11}^-$  (Figure 4) is considered to be the most ionic compound. Xenon(II) compounds with pentafluorides, claimed in the literature, are given in Table 1.

The isolation of the compounds  $2\text{XeF}_2 \cdot \text{VF}_5$  and  $2\text{XeF}_2 \cdot \text{TaF}_5$  was not confirmed. Stable 2:1 compounds were not obtained either in the  $\text{XeF}_2\text{--NbF}_5$  nor in the  $\text{XeF}_2\text{--TaF}_5$  systems.<sup>40</sup> The compound  $\text{XeF}_2 \cdot 2\text{OsF}_5$  was not prepared. Even the 1:1 compound is thermally unstable at room temperature and decomposes to  $2\text{XeF}_2 \cdot \text{OsF}_5$ , xenon, and osmium hexafluoride.

In the case of  $\text{AuF}_5$ , other compounds with a higher content of  $\text{AuF}_5$  could probably also be synthesized. Probably because  $\text{PF}_5$  is a relatively weak fluoroacid the

**Table 1** Xenon(II) compounds with pentafluorides

|                                    |                                   |                                    |
|------------------------------------|-----------------------------------|------------------------------------|

| $2\text{XeF}_2 \cdot \text{PtF}_5$ | $\text{XeF}_2 \cdot \text{PtF}_5$ | $\text{XeF}_2 \cdot 2\text{PtF}_5$ |
| $2\text{XeF}_2 \cdot \text{AuF}_5$ | —                                 | —                                  |
| $2\text{XeF}_2 \cdot \text{PF}_5$  | $\text{XeF}_2 \cdot \text{PF}_5$  | —                                  |
| $2\text{XeF}_2 \cdot \text{AsF}_5$ | $\text{XeF}_2 \cdot \text{AsF}_5$ | —                                  |
| $2\text{XeF}_2 \cdot \text{SbF}_5$ | $\text{XeF}_2 \cdot \text{SbF}_5$ | $\text{XeF}_2 \cdot 2\text{SbF}_5$ |
| $2\text{XeF}_2 \cdot \text{BiF}_5$ | $\text{XeF}_2 \cdot \text{BiF}_5$ | $\text{XeF}_2 \cdot 2\text{BiF}_5$ |
| —                                  | —                                 | $\text{XeF}_2 \cdot 2\text{BrF}_5$ |
| —                                  | $\text{XeF}_2 \cdot \text{IF}_5$  | $\text{XeF}_2 \cdot 2\text{IF}_5$  |

compounds  $2\text{XeF}_2 \cdot \text{PF}_5$  and  $\text{XeF}_2 \cdot \text{PF}_5$  were not established with certainty. All efforts to prepare a phase richer in  $\text{AsF}_5$  than  $\text{XeF}_2 \cdot \text{AsF}_5$  failed. Even the 1:1 compound loses  $\text{AsF}_5$  at room temperature to yield  $2\text{XeF}_2 \cdot \text{AsF}_5$ . In the system  $\text{XeF}_2\text{--SbF}_5$  a set of additional compounds was postulated ( $2\text{XeF}_2 \cdot 3\text{SbF}_5$ ,  $\text{XeF}_2 \cdot 3\text{SbF}_5$ ,  $\text{XeF}_2 \cdot 6\text{SbF}_5$ ) on the basis of the melting point–composition diagram. The molecular adducts,  $\text{XeF}_2 \cdot 2\text{BrF}_5$  and  $\text{XeF}_2 \cdot 9\text{BrF}_5$ , were also postulated on the basis of the melting point–composition diagram. The compound  $\text{XeF}_2 \cdot \text{IF}_5$  is a molecular adduct. The compound  $\text{XeF}_2 \cdot 2\text{IF}_5$  was not confirmed.

Single-crystal structures of the types  $\text{XeF}^+\text{MF}_6^-$  and  $\text{XeF}^+\text{M}_2\text{F}_{11}^-$  are shown in Figure 4. The structures in Figure 4 confirm that xenon difluoride donates a fluoride ion to the metal pentafluoride to generate the  $\text{MF}_6^-$  or  $\text{M}_2\text{F}_{11}^-$  salt, depending on the mole ratio of the reactants. When  $\text{XeF}_2$  is in excess, the  $\text{Xe}_2\text{F}_3^+$  cation (Figure 5) is formed. The V-shaped  $[\text{F--Xe--F--Xe--F}]^+$  cation is planar and symmetrical about the bridging fluorine atom. The intermolecular separations suggest that  $\text{F--Xe}^+\text{F}^-\text{Xe--F}^+$  is the major canonical form in the cation.

$\text{XeF}^+$  species in the  $\text{XeF}^+\text{MF}_6^-$  and  $\text{XeF}^+\text{M}_2\text{F}_{11}^-$  salts are characterized by a band or pair of bands in the Raman spectrum in the  $596\text{--}619\text{ cm}^{-1}$  region, and in the IR spectrum in the  $600\text{--}626\text{ cm}^{-1}$  region.  $\text{Xe}_2\text{F}_3^+$  is characterized by strong Raman bands in the Xe–F stretching region at  $\approx 593$  and  $580\text{ cm}^{-1}$ , and in the bending region at  $160\text{ cm}^{-1}$ .

**Figure 4** The molecular structures of (a)  $\text{XeF}^+\text{Sb}_2\text{F}_{11}^-$ , and (b)  $\text{XeF}^+\text{AsF}_6^-$

**Figure 5** Bond lengths and angles in  $\text{Xe}_2\text{F}_3^+$

## 5.5.3 Compounds with Tetrafluorides

In the system  $\text{XeF}_2$ –tetrafluorides, the set of compounds in Table 2 was claimed to exist. The existence of the compounds  $2\text{XeF}_2 \cdot \text{MF}_4$  ( $\text{M} = \text{Ti}, \text{Zr}, \text{Hf}, \text{Sn}$ ) was not confirmed.<sup>40</sup> Tetrafluorides are not sufficiently strong Lewis fluoroacids to stabilize compounds of the type  $(\text{XeF}_3^+)_2\text{MF}_6^{2-}$ . There is some evidence in the case of palladium of the possible existence of such a salt,<sup>41</sup> but it readily loses  $\text{XeF}_2$ . Even compounds of the type  $(\text{XeF}^+)_2\text{MF}_6^{2-}$  have not been isolated. There are several stable polymeric compounds of the type  $(\text{XeF}^+)_x(\text{MF}_5^-)_x$  (see Figure 6) and the type  $(\text{XeF}^+)_x(\text{M}_2\text{F}_9^-)_x$ .

Crystal structures have been determined only in the case of  $\text{XeF}_2 \cdot \text{CrF}_4$  (Figure 6) and  $\text{XeF}_2 \cdot \text{XeF}_4$ . Vibrational spectra show  $\text{XeF}_2 \cdot \text{CrF}_4$  to be only partially on the ionization pathway towards an  $\text{XeF}^+$  salt. The  $\text{XeF}_2 \cdot \text{XeF}_4$  is an adduct in which the component molecules closely resemble the molecules in the component fluoride crystals.

## 5.5.4 Compounds with Trifluorides, Difluorides, and Monofluorides

The compounds  $2\text{XeF}_2 \cdot \text{BF}_3$  and  $\text{XeF}_2 \cdot \text{BF}_3$  were reported in the literature, but they have not been confirmed.

**Table 2** Xenon(II) compounds with tetrafluorides

|                                     |                                     |
|-------------------------------------|-------------------------------------|
| $2\text{XeF}_2 \cdot \text{TiF}_4$  | $4\text{XeF}_2 \cdot \text{PdF}_4$  |
| $3\text{XeF}_2 \cdot 2\text{TiF}_4$ | $3\text{XeF}_2 \cdot \text{PdF}_4$  |
| $\text{XeF}_2 \cdot \text{TiF}_4$   | $2\text{XeF}_2 \cdot \text{PdF}_4$  |
| $\text{XeF}_2 \cdot 2\text{TiF}_4$  | $\text{XeF}_2 \cdot \text{PdF}_4$   |
| $2\text{XeF}_2 \cdot \text{ZrF}_4$  | $\text{XeF}_2 \cdot 2\text{PdF}_4$  |
| $2\text{XeF}_2 \cdot \text{HfF}_4$  | $\text{XeF}_2 \cdot 2\text{PtF}_4$  |

| $\text{XeF}_2 \cdot 2\text{MnF}_4$  | $\text{XeF}_2 \cdot 2\text{SnF}_4$  |
| $\text{XeF}_2 \cdot \text{RhF}_4$   | $\text{XeF}_2 \cdot \text{XeF}_4$   |

**Figure 6** Crystal structure of polymeric  $\text{XeF}_2 \cdot \text{CrF}_4$

## 5.5.5 Compounds with Oxide Tetrafluorides

$\text{XeF}_2$  adducts with the weak fluoride ion acceptor species  $\text{WOF}_4$  and  $\text{MoOF}_4$  have been prepared with the stoichiometry  $\text{XeF}_2 \cdot \text{MOF}_4$  and  $\text{XeF}_2 \cdot 2\text{MOF}_4$  ( $\text{M} = \text{Mo}, \text{W}$ ). Fluorine-19 NMR spectroscopy has been used to investigate their solution structures in different solvents. In  $\text{SO}_2\text{ClF}$  solution,  $\text{XeF}_2 \cdot n\text{MOF}_4$  ( $n = 1-4$ ) species were observed at low temperatures. The structures contain  $\text{Xe-FL-M}$  bridges that are nonlabile on the NMR timescale at low temperatures. In the adduct  $\text{XeF}_2 \cdot n\text{WOF}_4$  ( $n = 2, 3$ ), isomerization between oxygen and fluorine-bridged  $\text{Xe-F}$  groups was observed for the first time.  $\text{XeF}_2 \cdot \text{MOF}_4$  adducts solvolyze in  $\text{HSO}_3\text{F}$  at 193 K, yielding a new species, the fluorosulfate-bridged structure  $\text{FXeSO}_3\text{FMOF}_4$ , which is in equilibrium with  $\text{FXeSO}_3\text{F}$  and  $\text{MOF}_4$ .<sup>42</sup>

A molecular adduct  $\text{XeF}_2 \cdot \text{XeOF}_4$  is formed by the reaction between  $\text{XeF}_2$  and  $\text{XeOF}_4$ .<sup>43</sup> It is a white solid with a melting point of 302 K. The ‘semi-ionic’ lattice is similar to that of  $\text{XeF}_2 \cdot \text{IF}_5$ .

## 5.5.6 Compounds with Fluorosulfate and Related Groups

The preparation of monosubstituted  $\text{XeF}_2$  derivatives has generally involved the reaction between  $\text{XeF}_2$  and an appropriate anhydrous acid, according to equation (8). The driving force for equation (8) is the considerable exothermicity of formation of  $\text{HF}$  ( $\Delta H_f^\circ = -271.6 \text{ kJ mol}^{-1}$ ). The first compound of this type was  $\text{FXeSO}_3\text{F}$ , but later a whole set of these compounds was isolated. The ligands involved were  $-\text{OTeF}_5$ ,  $-\text{OSeF}_5$ ,  $-\text{OC}(\text{O})\text{CF}_3$ ,  $-\text{OPOF}_2$ , and  $-\text{OCIO}_3$ . The pentafluorotellurate is the most stable, but the perchlorate and the trifluoroacetate are kinetically unstable and detonate readily.

Disubstituted derivatives of  $\text{XeF}_2$  have also been isolated. These compounds are obtained by treating  $\text{XeF}_2$  with two moles of an anhydrous acid or by reacting  $\text{FXeL}$  with one mole of acid. The bis compounds are less stable than the monosubstituted species.

The bonding in  $\text{FXeOSO}_2\text{F}$  is essentially covalent, with little ionic contribution to the bonding. Mixed compounds of the type  $\text{R}^2\text{O-Xe-OR}^1$  have been detected in the  $^{129}\text{Xe}$  NMR spectra. The compound  $\text{F}_5\text{SeO-Xe-OTeF}_5$  exists only in equilibrium with the derivatives  $\text{Xe}(\text{OSeF}_5)_2$  and  $\text{Xe}(\text{OTeF}_5)_2$ .

Some monosubstituted derivatives of  $\text{XeF}_2$  can also form salts with strong Lewis acids. Unusual cations have been formed using this synthetic route. The reaction between xenon(II) fluoride orthopentafluorotellurate ( $\text{FXeOTeF}_5$ ) and  $\text{AsF}_5$  yields a bright-yellow solid  $\text{XeOTeF}_5^+\text{AsF}_6^-$  melting at 433 K.  $\text{FXeOTeF}_5$  is a poorer donor of  $\text{F}^-$  than  $\text{XeF}_2$ .

By reacting  $\text{XeF}^+\text{AsF}_6^-$  with  $\text{KSO}_3\text{F}$  in the mole ratio 2:1, the salt  $(\text{FXe})_2\text{SO}_3\text{F}^+\text{AsF}_6^-$  was formed. The  $(\text{FXe})_2\text{SO}_3\text{F}^+$

cation is not stable in excess  $\text{HSO}_3\text{F}$  at room temperature and slowly decomposes, liberating xenon gas.

### 5.5.7 Molecular Adducts of $\text{XeF}_2$

Several adducts of  $\text{XeF}_2$  have been prepared in which the  $\text{XeF}_2$  molecule is indistinguishable from the molecule in crystalline  $\text{XeF}_2$ . The following adducts were isolated:  $\text{XeF}_2 \cdot \text{XeF}_4$ ,  $\text{XeF}_2 \cdot \text{IF}_5$ ,  $\text{XeF}_2 \cdot \text{XeOF}_4$ ,  $\text{XeF}_2 \cdot (\text{XeF}^+\text{Sn}_2\text{F}_9^-)_2$ ,  $2\text{XeF}_2 \cdot \text{XeF}_5^+\text{AsF}_6^-$ ,  $\text{XeF}_2 \cdot \text{XeF}_5^+\text{AsF}_6^-$ , and  $\text{XeF}_2 \cdot (\text{XeF}_5^+\text{AsF}_6^-)_2$ . The adducts may be prepared by mixing the starting compounds in the appropriate molar proportions, or by fusing their mixture, or dissolving them in a suitable solvent.

All  $\text{XeF}_2$  molecular complexes owe their existence to appreciable coulombic interactions between the negatively charged F ligands and the positive center of the partner molecule.

## 5.6 Xenon(IV) Compounds

The fluorine ion donor ability of  $\text{XeF}_4$  has been shown to be less than that of  $\text{XeF}_2$  and  $\text{XeF}_6$ :  $\text{XeF}_6 > \text{XeF}_2 \gg \text{XeF}_4$ .<sup>25</sup> These findings are in agreement with the enthalpies of ionization<sup>44</sup> derived from photoionization studies (equations 9–11).

$$\Delta H^\circ = 9.45 \text{ eV}$$

$$\Delta H^\circ = 9.66 \text{ eV}$$

$$\Delta H^\circ = 9.24 \text{ eV}$$

The enthalpy of ionization of  $\text{XeF}_6$  is more than 0.6 eV lower than that anticipated on the basis of  $\text{XeF}_2$  and  $\text{XeF}_4$  data. This is compatible with the greater stability of  $\text{XeF}_5^+$  salts compared with  $\text{XeF}^+$  and  $\text{XeF}_3^+$ . It seems that the pseudooctahedral geometry of the  $\text{XeF}_5^+$  ion is especially favorable.

Although there is no doubt that  $\text{XeF}_6$  is the strongest fluoride ion donor, there is disagreement as to the relative fluoride ion donor abilities of  $\text{XeF}_2$  versus  $\text{XeF}_4$ . On the basis of the length, direction, and number of fluorine bridges in  $\text{XeF}^+$  and  $\text{XeF}_3^+$  salts, it has been concluded that the order of fluoride ion donor ability is  $\text{XeF}_2 < \text{XeF}_4 < \text{XeF}_6$ . That very few  $\text{XeF}_3^+$  salts have been isolated, and that those known are thermally less stable than their  $\text{XeF}_2$  relatives, contradicts this conclusion and supports the  $\text{F}^-$  donor strength being in the sequence  $\text{XeF}_4 < \text{XeF}_2 < \text{XeF}_6$ .

### 5.6.1 Compounds with $\text{XeF}_4$

$\text{XeF}_4$  only forms compounds with the strongest Lewis acids ( $\text{SbF}_5$  and  $\text{BiF}_5$ ). The compounds  $\text{XeF}_4 \cdot \text{MF}_5$  and  $\text{XeF}_4 \cdot 2\text{MF}_5$

Figure 7 The  $\text{XeF}_3^+\text{Sb}_2\text{F}_{11}^-$  structural unit

( $\text{M} = \text{Sb}, \text{Bi}$ ) have been isolated at room temperature, while the existence of the compound  $\text{XeF}_4 \cdot \text{AsF}_5$  has been claimed at low temperatures and in the presence of an excess of  $\text{AsF}_5$ . The compounds can be presented as  $\text{XeF}_3^+$  salts on the basis of the first crystal structure obtained in this system (Figure 7). The  $\text{XeF}_3^+$  cation is T-shaped and coordinated to the anion via a fluorine bridge, the length and polar character of which is determined by the Lewis acidity of the anion. The totally symmetric stretching vibration  $\nu_1$  of  $\text{XeF}_3^+$  is  $\approx 643 \text{ cm}^{-1}$ .

### 5.6.2 Compounds with $\text{XeOF}_2$

Cesium fluoride ( $\text{CsF}$ ) was added at 77 K to solid  $\text{XeOF}_2$  under a layer of  $\text{HF}$ .  $\text{CsF}$  dissolved upon warming to 195 K, forming  $\text{Cs}^+(\text{HF})_x\text{F}^-$ , which reacted with  $\text{XeOF}_2$  upon slow warming to 273 K. Under a dynamic vacuum to remove  $\text{HF}$ , the bright-yellow salt  $\text{Cs}^+\text{XeOF}_3^-$  was obtained. It is stable at room temperature for several hours. The Raman spectrum of  $\text{XeOF}_3^-$  has been assigned on the basis of  $\text{C}_{2v}$  symmetry.<sup>32</sup> Attempts to prepare the  $\text{XeOF}^+$  cation have failed. Addition of  $\text{AsF}_5$  to  $\text{XeOF}_2$  under a layer of  $\text{HF}$  resulted in the decomposition to  $\text{O}_2$  and  $\text{XeF}^+\text{AsF}_6^-$ .<sup>32</sup>

## 5.7 Xenon(VI) Compounds

The compounds obtained by the reaction of  $\text{XeF}_6$  or xenon(VI) oxide fluorides with Lewis acids and bases are described here.

### 5.7.1 $\text{XeF}_5^+$ and $\text{Xe}_2\text{F}_{11}^+$ Salts

Many synthetic routes have been used for the preparation of xenon(VI) fluoro complexes.

1. *Direct method.* The interaction of a binary fluoride with an excess of  $\text{XeF}_6$  in its melt. Several compounds have been prepared by using  $\text{XeF}_6$  not only as a fluorobase but

also as an oxidizing and fluorinating agent. In some cases, the xenon(VI) compounds have been prepared by mixing the component fluorides in a nonreducing solvent.

2. *Indirect method.* The corresponding binary fluoride is synthesized in situ in a very reactive 'molecular form'. In this case,  $\text{XeF}_6$  acts as a fluorinating agent by fluorine/oxygen exchange ( $\text{XeOF}_4$  formed) and in some cases also as an oxidizing agent. Hydrazinium or ammonium salts or oxides have been used as starting materials.
3. *Combined method.* In this case,  $\text{KrF}_2$  and  $\text{XeF}_6$  have been used simultaneously. This synthetic route is efficient in cases where the parent binary fluoride acceptor is itself thermodynamically unstable in the oxidation state in which the xenon(VI) fluoro compound is expected (e.g.  $(\text{XeF}_5^+)_2\text{NiF}_6^{2-}$ ), or in cases where the binary fluoride exists in the appropriate oxidation state but  $\text{XeF}_6$  is not strong enough to oxidize it to this state (e.g.  $\text{XeF}_5^+\text{AgF}_4^-$ ).

Xenon hexafluoride forms compounds with monomeric and polymeric anions. In the case of monomeric anions we have the following set of compounds:  $\text{Xe}_2\text{F}_{11}^+\text{MF}_6^-$ ,  $\text{XeF}_5^+\text{MF}_6^-$ ,  $\text{XeF}_5^+\text{M}_2\text{F}_{11}^-$ ,  $(\text{Xe}_2\text{F}_{11}^+)_2\text{MF}_6^{2-}$ ,  $(\text{XeF}_5^+)_2\text{MF}_6^{2-}$ ,  $(\text{Xe}_2\text{F}_{11}^+)_3\text{MF}_6^{3-}$  and  $(\text{XeF}_5^+)_3\text{MF}_6^{3-}$ . In the case of polymeric anions, with tetravalent fluorides, we have the following mole ratios:  $\text{XeF}_6:\text{MF}_4 = 4:3, 3:4, 1:2, 1:4$ , and with  $\text{MF}_3$  1:1 and 1:2. The compounds between  $\text{XeF}_6$  and  $\text{F}^-$  acceptors are given in Table 3. Estimates of stability, reaction activity, and solubility of  $(\text{XeF}_5^+)(\text{MF}_6^-)$  ( $M = \text{P-Bi, V-Ta}$ ) have been made based upon ab initio calculations.<sup>45</sup>

The adducts  $2\text{XeF}_6\cdot\text{MoF}_6$  and  $\text{XeF}_6\cdot\text{MoF}_6$  were established only from melting point–composition diagrams. The 4:1 compounds are  $\text{Xe}_2\text{F}_{11}^+$  salts, while the 1:4 compounds are  $\text{XeF}_5^+$  salts with polymeric anions. The compounds  $\text{XeF}_6\cdot\text{MF}_4$  ( $M = \text{Zr, Hf}$ ),  $\text{XeF}_6\cdot\text{MF}_3$  ( $M = \text{Sc, Fe, Ga, In}$ ), and  $\text{XeF}_6\cdot 2\text{MF}_3$  ( $M = \text{Al}$ ) are derived by the indirect synthetic route. The compounds  $6\text{XeF}_6\cdot\text{MF}_3$  ( $M = \text{Y, Ho, Er, Tm, Yb, Lu}$ ) and  $3\text{XeF}_6\cdot\text{MF}_3$  ( $M = \text{Y, Dy, Ho}$ ) are the first known monomeric salts of  $\text{Xe}_2\text{F}_{11}^+$  and  $\text{XeF}_5^+$ , respectively, with a metal in the 3+ valence state. The compound  $\text{XeF}_6\cdot\text{AuF}_3$ ,<sup>46</sup> together with  $\text{XeF}_6\cdot\text{AuF}_5$ , represents the first instance of  $\text{XeF}_5^+$  occurring with two different valence states of a metal.

As may be seen from the structures of  $(\text{Xe}_2\text{F}_{11}^+)\text{AuF}_6^-$  and  $(\text{Xe}_2\text{F}_{11}^+)_2\text{NiF}_6^{2-}$  (Figure 8), the group  $\text{Xe}_2\text{F}_{11}^+$  consists of two similar  $\text{XeF}_5^+$  groups linked by a bridging F species (formally  $\text{F}^-$ ). It should be noted that the  $\text{XeF}_5^+$  species occurring in the structures of  $\text{Xe}_2\text{F}_{11}^+$  or  $\text{XeF}_5^+$  salts are similar in shape but the total coordination of the cation varies from one salt to another. The xenon atom in  $\text{XeF}_5^+$  retains a nonbonding valence-electron pair that is evidently sterically active so that the Xe atom is pseudooctahedrally coordinated with five fluorine atoms and the sterically active valence-electron pair. Negatively charged species are attracted most strongly when positioned off axis, as shown in Figure 9.

This model does not explain why certain anions (like  $\text{RuF}_6^-$ ,  $\text{AuF}_6^-$ , and  $\text{PtF}_6^-$ ) provide four F ligands (Figure 10) to coordinate to  $\text{XeF}_5^+$ , whereas  $\text{PdF}_6^{2-}$ ,  $\text{NiF}_6^{2-}$ , and  $\text{AsF}_6^-$  provide only three, and  $\text{NiF}_6^{2-}$  in the structure  $(\text{Xe}_2\text{F}_{11}^+)_2\text{NiF}_6^{2-}$  (Figure 8) only two. When  $\text{XeF}_5^+$  makes three bridging linkages to two different anions, the ring

**Figure 8** The structural units of (a)  $\text{Xe}_2\text{F}_{11}^+\text{AuF}_6^-$ , and (b)  $(\text{Xe}_2\text{F}_{11}^+)_2\text{NiF}_6^{2-}$

**Table 3** Xenon(VI) compounds with  $\text{F}^-$  acceptors

|                                                                                              |

**Figure 9** Shape of the  $\text{XeF}_5^+$  ion based on steric activity of the nonbonding xenon valence-electron pair. Arrows indicate directions of maximum polarizing effect

**Figure 10** The  $\text{XeF}_5^+$  and  $\text{RuF}_6^-$  structural units and the coordination of  $\text{XeF}_5^+$

**Figure 11** Configuration and bond distances for  $\text{XeF}_5^+\text{AsF}_6^-$

system shown for  $\text{XeF}_5^+\text{AsF}_6^-$  in Figure 11 occurs. That same ring appears repeatedly in the  $(\text{XeF}_5^+)_2\text{PdF}_6^{2-}$  structure

(Figure 12a), where each  $\text{XeF}_5^+$  is similarly connected to two separate anions. In the  $(\text{XeF}_5^+)_2\text{NiF}_6^{2-}$  structure (Figure 12b), however, one of the cations is coordinated to two separate anions to again generate the  $\text{XeF}_5^+\text{AsF}_6^-$ -type ring, but the other  $\text{XeF}_5^+$  makes its three bridge bonds to one octahedral face of one anion. This creates discrete  $(\text{XeF}_5)_4(\text{NiF}_6)_2$  clusters. The structure of  $(\text{XeF}_5^+\text{CrF}_5^-)_4\text{XeF}_4$  shows that this is an  $\text{XeF}_4$  molecular adduct of a  $\text{XeF}_5^+$  salt (Figure 13). This

**Figure 12** The structural units (a)  $(\text{XeF}_5^+)_2\text{PdF}_6^{2-}$  and (b)  $(\text{XeF}_5^+)_2\text{NiF}_6^{2-}$

**Figure 13**  $\text{XeF}_4$  environment in  $(\text{XeF}_5^+\text{CrF}_5^-)_4\text{XeF}_4$

structure is of particular interest in showing for the first time an appreciable deformation of the  $\text{XeF}_5^+$  cation. In addition, the anion consists of an infinite chain of distorted  $\text{CrF}_4(\text{F}_{0.5})_2^-$  octahedra that alternately share *cis* and *trans* vertices.

Vibrational spectroscopy (especially Raman) has been an important tool in the characterization of  $\text{Xe}_2\text{F}_{11}^+$  and  $\text{XeF}_5^+$  salts. The  $\text{Xe}_2\text{F}_{11}^+$  species behave vibrationally like two weakly coupled  $\text{XeF}_5^+$  species. The F bridging of the two  $\text{XeF}_5^+$  groups in the  $\text{Xe}_2\text{F}_{11}^+$  cation is characterized by a 'bridge stretch' at  $\approx 360\text{ cm}^{-1}$ . The full assignments for the fundamentals is available.<sup>47,48</sup>

### 5.7.2 $\text{XeF}_7^-$ and $\text{XeF}_8^{2-}$ Salts

Complexes of  $\text{XeF}_6$  with fluoride ion donors, for example,  $\text{NO}_2\text{F}$ ,  $\text{NOF}$ , and alkali metal fluorides (with the exception of  $\text{LiF}$ ), are listed in Table 4. On the basis of Raman spectroscopy, the compound  $2\text{NOF}\cdot\text{XeF}_6$  could be written as  $(\text{NO}^+)_2\text{XeF}_8^{2-}$ . This is supported by its crystal structure. The anion  $\text{XeF}_8^{2-}$  can be described as a slightly distorted Archimedean antiprism with Xe–F distances ranging from 1.946 to 2.099 Å. The steric activity of the nonbonding xenon valence-electron pair is not convincingly present.  $\text{NF}_4^+\text{XeF}_7^-$  decomposes to  $\text{NF}_3$ ,  $\text{F}_2$ , and  $\text{XeF}_6$ . Evidence for  $(\text{NF}_4^+)_2\text{XeF}_8$  as an intermediate has been given.

### 5.7.3 Xenon(VI) Oxyfluoro Cations: $\text{XeOF}_3^+$ , $\text{XeO}_2\text{F}^+$

$\text{XeOF}_4\cdot 2\text{SbF}_5$  was prepared by the reaction of  $\text{XeOF}_4$  with an excess of  $\text{SbF}_5$  at temperatures higher than room temperature, followed by removal of volatiles to constant weight at room temperature. A colorless solid with mp 334–338 K was obtained.  $\text{XeOF}_4\cdot\text{SbF}_5$  was obtained by the reaction of  $\text{XeOF}_4\cdot 2\text{SbF}_5$  with an excess of  $\text{XeOF}_4$  at temperatures a little above room temperature and removal of volatiles to constant weight at room temperature. A colorless solid with mp 377–378 K was obtained.<sup>49</sup> On the basis of their Raman spectra, it has been concluded that the compounds are ionic and contain the  $\text{XeOF}_3^+$  cation. The structure of  $\text{XeOF}_3^+$  is represented on a trigonal bipyramidal model with the nonbonding valence-electron pair and the oxygen ligand in equatorial sites. It is a geometric relative of  $\text{XeF}_3^+$ .

$\text{SbF}_5$  and  $\text{XeO}_2\text{F}_2$  in the mole ratio 2:1 were allowed to react in HF solution. A white solid was obtained after removal of the solvent.  $\text{XeO}_2\text{F}_2\cdot 2\text{SbF}_5$ , is unstable at room

temperature, decomposing to  $\text{XeF}^+\text{Sb}_2\text{F}_{11}^-$  and oxygen. The Raman spectrum of the compound  $\text{XeO}_2\text{F}_2\cdot 2\text{SbF}_5$  is consistent with the 'ionic' formulation  $\text{XeO}_2\text{F}^+\text{Sb}_2\text{F}_{11}^-$ . Vibrational spectroscopic evidence is consistent with the cation  $\text{XeO}_2\text{F}^+$  having a pyramidal (pseudotetrahedral) geometry. No direct evidence for fluorine bridging was obtained. The Raman spectrum is available.<sup>50</sup>

### 5.7.4 Xenon(VI) Oxyfluoro Anions: $\text{XeOF}_5^-$ , $(\text{XeOF}_4)_3\text{F}^-$ , $\text{XeO}_2\text{F}_3^-$ , and $\text{XeO}_3\text{X}^-$ ( $\text{X} = \text{F}, \text{Cl}, \text{Br}$ )

$\text{CsF}$  reacts with an excess of  $\text{XeOF}_4$  at room temperature yielding  $\text{CsF}\cdot 3\text{XeOF}_4$ , a white solid. This product is stable in a dynamic vacuum at 273 K when the excess  $\text{XeOF}_4$  is pumped away, but decomposes at room temperature in a static vacuum to  $\text{CsF}\cdot\text{XeOF}_4$  and  $\text{XeOF}_4$ .<sup>51</sup> On the basis of the Raman spectra,  $\text{CsF}\cdot\text{XeOF}_4$  is best formulated as the salt  $\text{Cs}^+\text{XeOF}_5^-$ . The presence of a single, sharp  $\text{Xe}=\text{O}$  stretching mode at ca.  $900\text{ cm}^{-1}$  in  $\text{CsF}\cdot 3\text{XeOF}_4$  indicates that all three  $\text{XeOF}_4$  molecules are equivalently bonded to a central fluorine ion, thus implying an anion  $(\text{XeOF}_4)_3\text{F}^-$ .

On slow warming of a solution of  $\text{XeOF}_2$  in HF from 210 to 273 K over a period of 20 h, pure  $\text{XeOF}_2$  decomposes to  $\text{XeF}_2$  and  $\text{XeO}_2\text{F}_2$ , which can further react with  $\text{Cs}^+(\text{HF})_x\text{F}^-$  dissolved in HF yielding  $\text{Cs}^+\text{XeO}_2\text{F}_3^-$ . The probable structure of  $\text{XeO}_2\text{F}_3^-$  is pseudooctahedral, with both oxygens in the axial positions and with the three fluorine atoms and the sterically active lone pair in equatorial positions.<sup>32</sup>

Hydrolysis of  $\text{Cs}^+\text{XeOF}_5^-$  or  $\text{CsXeF}_7^-$  leads to the compound  $\text{CsF}\cdot\text{XeO}_3$ . Single-crystal structure analysis of  $\text{KFXeO}_3$  showed that the compound is a polymer,  $[\text{K}^+]_n[\text{XeO}_3\text{F}^-]_n$ . A more convenient method of preparation mixes appropriate amounts of the aqueous solutions of  $\text{XeO}_3$  and metal fluoride (MF), subsequent evaporation yielding crystals of the salts. A series of compounds of the type  $\text{M}^+[\text{XeO}_3\text{X}^-]$  with  $\text{M} = \text{Cs}, \text{Rb}, \text{K}$  and  $\text{X} = \text{F}, \text{Cl}, \text{Br}$  is known. The thermal stability of these salts decreases with increasing atomic weight of the halogen. The fluoride salts are stable to 473 K, but decompose to xenon, oxygen, and alkali fluoride above 533 K. The chloride xenates begin to decompose at 423 K, while the bromo salt is unstable even at room temperature.

## 5.8 Xenon(VIII) Compounds

Xenon(VIII) oxyfluoro anions or cations have not yet been isolated.

## 5.9 Xenon Compounds with Bonds to Nitrogen and Carbon

### 5.9.1 Xe–N Bonding

The reaction of  $\text{XeF}_2$  with  $\text{HN}(\text{SO}_2\text{F})_2$  proceeds at 273 K, yielding  $\text{FXeN}(\text{SO}_2\text{F})_2$  and HF.<sup>52</sup>  $\text{FXeN}(\text{SO}_2\text{F})_2$  was the first

**Table 4** Xenon(VI) compounds with  $\text{F}^-$  donors

compound prepared with a Xe–N bond. The Xe–N and Xe–F distances are 2.200(3) and 1.967(3) Å, respectively with an F–Xe–N angle of 178.1(1)°. Like its XeF<sub>2</sub> precursor, the molecule exhibits fluoride ion donor properties. In reactions with Lewis acids, for example, AsF<sub>5</sub>, SbF<sub>5</sub>, and so on, the following salts have been obtained: XeN(SO<sub>2</sub>F)<sub>2</sub><sup>+</sup>AsF<sub>6</sub><sup>−</sup>, XeN(SO<sub>2</sub>F)<sub>2</sub><sup>+</sup>Sb<sub>3</sub>F<sub>16</sub><sup>−</sup>, and F[XeN(SO<sub>2</sub>F)<sub>2</sub>]<sub>2</sub><sup>+</sup>AsF<sub>6</sub><sup>−</sup>. These cations are less stable than their XeF<sup>+</sup> and Xe<sub>2</sub>F<sub>3</sub><sup>+</sup> counterparts. The reaction to prepare the disubstituted compound Xe[N(SO<sub>2</sub>F)<sub>2</sub>]<sub>2</sub> is much slower and should be performed at lower temperatures because Xe[N(SO<sub>2</sub>F)<sub>2</sub>]<sub>2</sub> decomposes rapidly near room temperature to xenon and [N(SO<sub>2</sub>F)<sub>2</sub>]<sub>2</sub>.

A new class of Xe–N bonded compounds is obtained by the interaction of the electron lone pair of a nitrile with the Lewis acid XeF<sup>+</sup>.<sup>53</sup> The cationic adducts RC≡N–XeF<sup>+</sup> with R = H, Me, CH<sub>2</sub>F, Et, C<sub>2</sub>F<sub>5</sub>, C<sub>3</sub>F<sub>7</sub>, and Ph have been isolated by the reaction of the appropriate nitrile with XeF<sup>+</sup>AsF<sub>6</sub><sup>−</sup> or Xe<sub>2</sub>F<sub>3</sub><sup>+</sup>AsF<sub>6</sub><sup>−</sup> in AHF at low temperatures.

Two additional xenon–nitrogen bonded cations represent unique examples of noble gas atoms functioning as aromatic ring substituents.<sup>54</sup> Equimolar amounts of XeF<sup>+</sup>AsF<sub>6</sub><sup>−</sup> and 4-RC<sub>5</sub>F<sub>4</sub>N (R = F or CF<sub>3</sub>) react in AHF at 243–253 K, yielding 4-RC<sub>5</sub>F<sub>4</sub>N–XeF<sup>+</sup>AsF<sub>6</sub><sup>−</sup>. Low-temperature Raman and <sup>129</sup>Xe, <sup>19</sup>F, and <sup>14</sup>N NMR spectroscopic results are consistent with planar cations in which the xenon atom is coordinated to the aromatic ring through the lone pair of electrons on the nitrogen ligand.

### 5.9.2 Xe–C Bonding

Compounds with bonding between carbon and Xe (II, IV) rely upon the maintenance of a partial positive charge on the Xe atom. A recent review detailed the full range and reactivity of these compounds so only a representative group will be described here.<sup>55,56</sup> The first established stable system with a xenon–carbon bond is the salt [C<sub>6</sub>F<sub>5</sub>Xe]<sup>+</sup>[C<sub>6</sub>F<sub>5</sub>BF<sub>3</sub>]<sup>−</sup>.<sup>57</sup> It can be prepared by nucleophilic displacement of fluorine in XeF<sub>2</sub> using B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> as an aryl-transfer reagent. The product is a colorless solid, stable at temperatures lower than 243 K. Other aryl groups (e.g. monosubstituted phenyl groups, XC<sub>6</sub>H<sub>4</sub>) can be used to synthesize salts of the type [XC<sub>6</sub>H<sub>4</sub>Xe]<sup>+</sup>[(XC<sub>6</sub>H<sub>4</sub>)<sub>2</sub>BF<sub>2</sub>]<sup>−</sup>. However, salts with the [C<sub>6</sub>F<sub>5</sub>Xe]<sup>+</sup> cation are significantly more stable and useful than those with [XC<sub>6</sub>H<sub>4</sub>Xe]<sup>+</sup>.<sup>58</sup> The stability of the latter salts increases with decreasing F<sup>−</sup> donor ability of the anion. In the absence of nucleophilic aryl groups in the anion, the thermal stability increases significantly. [C<sub>6</sub>F<sub>5</sub>Xe]<sup>+</sup>AsF<sub>6</sub><sup>−</sup> melts without decomposition at 370–371 K and the viscous melt is stable to 398 K. Recently, C<sub>6</sub>F<sub>5</sub>XeO<sub>2</sub>CC<sub>6</sub>F<sub>5</sub> was reported.<sup>59</sup> Xe is linearly bonded by C (2.122 Å) and O (2.367 Å) and an intramolecular Xe–O contact of 3.142 Å is formed by the acyloxy group. Intermolecular Xe–O bridges (3.237 Å) form pairs of the molecules in the solid.

Of related interest is a recent study indicating that SiF<sub>3</sub><sup>+</sup> combines with Xe, Kr, and Ar in the gas phase to form the complexes FNgSiF<sub>3</sub>.<sup>60</sup> Experimental and theoretical results indicated that FXeSiF<sub>3</sub> might be stable. Interestingly, similar reactions with CF<sub>3</sub><sup>+</sup> did not form noble gas compounds.

### 5.10 Xenates and Perxenates

Xenates are salts of xenic acid, (hypothetically Xe(OH)<sub>6</sub>). Aqueous XeO<sub>3</sub> solutions (xenic acid) are prepared by hydrolysis of XeF<sub>6</sub> (see Section 5.2.1). XeO<sub>3</sub> is one of the strongest known oxidants in aqueous media. The monoalkali xenates MHXeO<sub>4</sub>·1.5H<sub>2</sub>O (M = Na, K, Rb, Cs) are prepared by titration of xenic acid with alkali hydroxide solution. Species such as HXeO<sub>4</sub><sup>−</sup> and H<sub>5</sub>XeO<sub>6</sub><sup>−</sup> are possibly produced in this titration. The xenates(VI) are reported to be stable at room temperature in an inert atmosphere, but they disproportionate to xenon(0) and xenon(VIII) in air. They are thermally stable up to 373 or even 423 K. In some cases, they detonate.

CsHXeO<sub>4</sub> has been prepared by the reaction of xenon trioxide with aqueous cesium hydroxide in the presence of fluoride ion. The role of the fluoride ion in the preparation of CsHXeO<sub>4</sub> is not clear, but it seems that it prevents the formation of perxenate. In the absence of the fluoride ion, xenon trioxide and cesium hydroxide form a mixed perxenate and xenate salt. CsHXeO<sub>4</sub> is stable in air.

Perxenates were not prepared by oxidizing xenon with powerful oxidizers in aqueous media. The only preparative routes are by way of the xenon fluorides (XeF<sub>6</sub> or XeF<sub>4</sub>). Hydrolysis of XeF<sub>6</sub> in strongly alkaline media generates xenon gas and hydrated perxenate as a precipitated solid (equation 12). The most efficient synthesis of perxenate was by using ozone to oxidize XeO<sub>3</sub> in a solution of 1 M alkali hydroxide. Na<sub>4</sub>XeO<sub>6</sub> is a colorless solid, nearly insoluble in water. It contains 0.6 to 9 molecules of H<sub>2</sub>O per xenon atom, depending on the drying procedure.

The perxenates are colorless, thermally stable solids. Anhydrous sodium perxenate can be obtained at 373 K. It decomposes at 633 K. The corresponding barium salt decomposes at about 570 K. Perxenate solutions are powerful and rapid oxidizing agents. Xenon(VIII) is reduced to xenon(VI). Oxidation processes in acid media are more effective, but they must be fast enough to compete with decomposition of the perxenate, which is also rapid in acid.

The crystal structures of Na<sub>4</sub>XeO<sub>6</sub>·6H<sub>2</sub>O, Na<sub>4</sub>XeO<sub>6</sub>·8H<sub>2</sub>O, and K<sub>4</sub>XeO<sub>6</sub>·9H<sub>2</sub>O have been determined. The perxenate ion is octahedral. The water of the hydrates is coordinated to the cations and hydrogen-bonded to the perxenate oxygen ligands. The Xe–O bond lengths in the octahedra are in the

range 1.84–1.88 Å. This is much longer than in tetrahedral  $\text{XeO}_4$  (1.74 Å) or pseudotetrahedral  $\text{XeO}_3$  (1.76 Å).

### 5.11 Xenon Chlorides and Bromides

$\text{XeCl}_2$  has been prepared by high-frequency discharge of the mixture of Xe,  $\text{F}_2$ , and  $\text{SiCl}_4$  or  $\text{CCl}_4$  in the mole ratio 1:1:1 at 193 K.<sup>61</sup> The compound has also been prepared using the matrix-isolation technique and microwave discharge of a xenon–chlorine mixture.<sup>62</sup>  $\text{XeCl}_2$  is characterized by IR absorption at  $313\text{ cm}^{-1}$  ( $\nu_3$ , asymmetric Xe–Cl stretch), observed in the spectrum of the matrix-isolated material at 20 K, and matrix Raman at  $253\text{ cm}^{-1}$  ( $\nu_1$ , symmetrical Xe–Cl stretch). The greater bond energy of  $\text{Cl}_2$  relative to  $\text{F}_2$  (242 vs. 158  $\text{kJ mol}^{-1}$ ) and the lower thermochemical bond energy of chlorides relative to fluorides account for the low thermodynamic stability of  $\text{XeCl}_2$ .

Xenon tetrachloride and xenon dibromide have been detected by (see *Mössbauer Spectroscopy*) as products of the  $\beta$ -decay of their  $^{129}\text{I}$  relatives (equation 13).

More recently, the matrix isolation of the linear, centrosymmetric, compounds,  $\text{HNgX}$  (where  $\text{Ng} = \text{Xe}, \text{Kr}, \text{Ar}$  and  $\text{X} = \text{halide}$ ) has been achieved.<sup>63,64</sup> A theoretical study reveals that HF hydrogen bonding will be fairly strong to the fluoride of  $\text{HNgF}$ .<sup>65</sup>

## 6 THE CHEMISTRY OF KRYPTON

Compounds of Kr are currently only known for the 2+ oxidation state.<sup>66</sup>

### 6.1 Krypton Difluoride

Krypton difluoride was first prepared by Turner and Pimentel<sup>67</sup> by UV photolysis of fluorine suspended in a solid mixture of argon and krypton at 20 K. Because krypton difluoride is thermodynamically unstable, all effective syntheses have to be carried out at low temperatures (e.g. 77 K). Methods used for the preparation of  $\text{KrF}_2$  in the laboratory include electric discharge of a gaseous mixture of krypton and fluorine at low temperature and pressure (yield  $250\text{ mg h}^{-1}$ ), high-frequency discharge in a mixture of krypton and  $\text{CF}_2\text{Cl}_2$ , irradiation of fluorine–krypton mixtures with 1.5 MeV electrons, or 10 MeV protons, thermal decomposition of  $\text{F}_2$  at 950 K on a nickel wire (yield  $6\text{ g h}^{-1}$ ), and, less efficiently, by exposure to sunlight.

A very efficient method for the preparation of  $\text{KrF}_2$  on a larger scale has been developed (30–40 g per batch).<sup>68</sup> It is based on the irradiation of a liquified mixture of fluorine and krypton with near-UV light at 77 K. The mole ratio of the krypton–fluorine mixture is 4:1 and the yield about  $1\text{ g h}^{-1}$  of  $\text{KrF}_2$ .

Krypton difluoride is colorless in the solid and vapor phase and it decomposes at temperatures above 250 K. The rate of decomposition is dependent upon the pretreatment of the reaction vessel. Because  $\text{KrF}_2$  has some vapor pressure even at temperatures between 220 and 230 K, it will start to react if the reaction vessel has not been thoroughly pretreated with  $\text{KrF}_2$ . Krypton difluoride has the lowest average bond energy of any known fluoride. The atomization energy of  $\text{KrF}_2$  ( $\Delta H_{\text{at}} = 98\text{ kJ mol}^{-1}$ ) is smaller than the dissociation energy of elemental fluorine ( $\Delta H_{\text{diss}} = 158\text{ kJ mol}^{-1}$ ), thus indicating that krypton difluoride is closest in activity to atomic fluorine. Its  $\Delta H_{\text{f}} = 60\text{ kJ mol}^{-1}$ .

$\text{KrF}_2$  is a symmetrical linear molecule ( $D_{\infty h}$ ). In the crystal,  $\text{KrF}_2$  molecules are aligned in planes perpendicular to the tetrad axes of the unit cell. Within these sheets, nearest neighbor molecules are aligned roughly perpendicular to one another, thus placing the negatively charged F ligands close to the positively charged krypton atoms of neighboring molecules (Figure 14).

Hydrolysis of  $\text{KrF}_2$  proceeds analogously to the hydrolysis of  $\text{XeF}_2$  in basic solution (equation 14). This same reaction occurs rapidly in acid solution, in contrast to the behavior of  $\text{XeF}_2$ , which dissolves and may persist unhydrolyzed for an extended period of time. No ionic species containing krypton remain in solution after hydrolysis.

### 6.2 Krypton Oxide

No krypton oxide has yet been isolated and characterized. When  $\text{KrF}_2$  is hydrolyzed slowly with moist air, it is possible

Figure 14 Unit cell of  $\text{KrF}_2$

that some very unstable  $\text{KrO}$  is formed, which decomposes explosively.

### 6.3 Krypton(II) Compounds

Krypton(II) compounds are those krypton–fluorine compounds which exhibit a significant amount of ionic character and can be described either as  $\text{KrF}^+$  and  $\text{Kr}_2\text{F}_3^+$  salts,  $\text{KrF}_2$  adducts with these salts, or molecular adducts of  $\text{KrF}_2$  with certain binary fluorides. All known krypton(II) compounds are listed in Table 5.

Krypton complexes may be prepared directly by the reaction of  $\text{KrF}_2$  with the appropriate binary fluoride, neat or in solution. In some cases, binary fluorides have been prepared in situ using  $\text{KrF}_2$  as the fluorinating agent. So far, no X-ray crystal structure of any  $\text{KrF}_2$  complex has been determined, and the characterization of the complexes has rested largely on vibrational spectroscopy. Raman spectroscopy has been especially valuable in studies of these compounds, all of which are of low thermal stability.

Observed Raman and IR frequencies for  $\text{Kr}^{\text{II}}$  compounds are best assigned on the basis of ionic formulations:  $\text{KrF}^+\text{M}_2\text{F}_{11}^-$ ,  $\text{KrF}^+\text{MF}_6^-$ , and  $\text{Kr}_2\text{F}_3^+\text{MF}_6^-$ . The appearance of  $\text{KrL}\cdot\text{F}$  and  $\text{ML}\cdot\text{F}$  bridge-stretching and  $\text{F}-\text{KrL}\cdot\text{F}$  bending modes points to a strong interaction between the cation and anion, indicative of some covalent character in that bonding. For the  $\text{KrF}^+$  salts, the stretching vibration is in the range from  $626\text{ cm}^{-1}$  (in the case of  $\text{KrF}^+\text{Sb}_2\text{F}_{11}^-$ ) to  $597\text{ cm}^{-1}$  (in the case of  $\text{KrF}_2\cdot 2\text{NbF}_5$ ).

The spectra of the  $\text{Kr}_2\text{F}_3^+$  cation have been correlated with those of the  $\text{Xe}_2\text{F}_3^+$  species, but additional peaks, which have no equivalents in the xenon spectra, suggest that  $\text{Kr}_2\text{F}_3^+$  is less symmetrical than its xenon analog, with one longer and weaker  $\text{Kr}-\text{F}$  bond and one shorter and stronger  $\text{Kr}-\text{F}$  bond. An alternative interpretation is that this cation

involves a distorted  $\text{KrF}_2$  molecule fluorine-bridged to a  $\text{KrF}^+$  cation.<sup>20</sup>

Krypton difluoride forms complexes mostly with Lewis acid pentafluorides in the mole ratio 2:1, 1:1, and 1:2. In addition, there are a number of compounds in which additional  $\text{KrF}_2$  appears to be weakly associated, probably with the cationic part of the compound. Recently, the first adducts of  $\text{KrF}_2$  with tetravalent fluorides have also been isolated and characterized:  $2\text{KrF}_2\cdot\text{MnF}_4$  and  $\text{KrF}_2\cdot\text{MnF}_4$ . The 1:1 compound is most probably  $\text{KrF}^+\text{MnF}_5^-$  with a polymeric anion.<sup>69</sup> Claims for the compounds  $2\text{KrF}_2\cdot\text{TiF}_4$  and  $2\text{KrF}_2\cdot\text{SnF}_4$  have not been supported by any characterizational evidence.

The highly polar bonds of  $\text{KrF}_2$  also give rise to adducts with other molecules possessing highly polar bonds; compounds include  $\text{KrF}_2\cdot\text{BrF}_5$  and  $\text{KrF}_2\cdot\text{XeF}_6$ .

The first krypton difluoride–metal oxide fluoride adducts have been prepared by reaction of  $\text{KrF}_2$  with  $\text{MOF}_4$  ( $\text{M} = \text{Mo}, \text{W}$ ) in  $\text{SO}_2\text{ClF}$  solution at low temperatures. Raman spectra of the solid  $\text{KrF}_2\cdot\text{MoOF}_4$  and  $\text{KrF}_2\cdot\text{WOF}_4$  indicate that these compounds are not  $\text{KrF}^+$  salts, but are more covalent fluorine-bridged structures. The  $^{19}\text{F}$  NMR spectra of  $\text{KrF}_2\cdot n\text{MoOF}_4$  ( $n = 1-3$ ) and  $\text{KrF}_2\cdot\text{WOF}_4$  indicate also that these complexes are best formulated as essentially covalent structures containing  $\text{KrL}\cdot\text{FL}\cdot\text{M}$  bridges and mononuclear or polynuclear metal oxide fluoride species.

### 6.4 Krypton Compounds with Bonds to Oxygen and Nitrogen

$\text{Kr}(\text{OTeF}_5)_2$  is the first krypton compound containing a krypton–oxygen bond. It was prepared by the reaction between  $\text{KrF}_2$  and  $\text{B}(\text{OTeF}_5)_3$  at 183–161 K in  $\text{SO}_2\text{ClF}$  as solvent.<sup>70</sup>

It is interesting that the compound containing the first krypton–nitrogen bond was synthesized before a compound with a krypton–oxygen bond. The first compound with a krypton–nitrogen bond was synthesized at low temperatures in  $\text{BrF}_5$  solvent according to a general synthetic approach (equation 15). Each nitrogen base found capable of bonding with  $\text{KrF}^+$  is oxidatively resistant and possesses a first adiabatic ionization potential close to or exceeding the estimated *Electron Affinity* of  $\text{KrF}^+$  (13.2 eV). The first adiabatic ionization potential of  $\text{HC}\equiv\text{N}$  is 13.59 eV. The low basicity of the nitrogen atoms in these bases gives the krypton–nitrogen bond significant ionic character. This is important for the thermal stability of such a cation.<sup>71</sup> Compounds with krypton–carbon bonds have not yet been isolated.

**Table 5** Krypton(II) compounds

|                                          |                                                                   |
|------------------------------------------|-------------------------------------------------------------------|
| $2\text{KrF}_2\cdot\text{TiF}_4$         | $(x\text{KrF}_2\cdot\text{KrF})^+\text{Nb}_2\text{F}_{11}^-$      |
| $2\text{KrF}_2\cdot\text{MnF}_4$         | $\text{KrF}^+\text{Nb}_2\text{F}_{11}^-$                          |

| $\text{KrF}_2\cdot\text{XeF}_6$          | $\text{KrF}^+\text{AsF}_6^-$                                      |
| $\text{KrF}^+\text{RuF}_6^-$             | $(x\text{KrF}_2\cdot\text{Kr}_2\text{F}_3^+)\text{SbF}_6^-$       |
| $\text{KrF}^+\text{Ru}_2\text{F}_{11}^-$ | $(x\text{KrF}_2\cdot\text{KrF}^+)\text{SbF}_6^-$                  |
| $\text{KrF}^+\text{RhF}_6^-$             | $\text{Kr}_2\text{F}_3^+\text{SbF}_6^-$                           |
| $\text{KrF}^+\text{PdF}_6^-$             | $\text{KrF}^+\text{SbF}_6^-$                                      |
| $\text{KrF}^+\text{PtF}_6^-$             | $\text{KrF}^+\text{Sb}_2\text{F}_{11}^-$                          |
| $\text{KrF}^+\text{Pt}_2\text{F}_{11}^-$ |                                                                   |
| $\text{KrF}^+\text{AuF}_6^-$             |                                                                   |
| $\text{KrF}^+\text{BiF}_6^-$             |                                                                   |
| $\text{KrF}^+\text{BF}_4^-$              |                                                                   |

## 7 THE CHEMISTRY OF RADON

There are no stable isotopes of radon and the longest lived 'natural' isotope,  $^{222}\text{Rn}$ , has a half-life of only 3.83 days. Experimental difficulties arise not only from the radiation hazard, but also from the decomposition caused by the radiation. The most detailed review of radon chemistry, to early 1981, was written by Stein.<sup>72</sup>

Radon forms a series of clathrate compounds similar to those of krypton, xenon, and argon (e.g.  $\text{Rn}\cdot 6\text{H}_2\text{O}$ ,  $\text{Rn}\cdot 3\text{C}_6\text{H}_5\text{OH}$ ,  $\text{Rn}\cdot 3p\text{-ClC}_6\text{H}_4\text{OH}$ ).

$^{222}\text{Rn}$  decays by  $\alpha$  emission and exhibits only slight  $\gamma$  activity when freshly separated from radium. The short-lived  $\beta$ - and  $\gamma$ -emitting daughters  $^{214}\text{Pb}$  and  $^{214}\text{Bi}$ , as well as the short-lived  $\alpha$ -emitting daughters  $^{218}\text{Po}$  and  $^{214}\text{Po}$ , grow into equilibrium with  $^{222}\text{Rn}$  within 4 h. The energetic (1.8 MeV)  $\gamma$ -ray of  $^{214}\text{Bi}$  is frequently used to trace  $^{222}\text{Rn}$ .

Millicurie and curie amounts of radon react spontaneously with gaseous fluorine at room temperature and with liquid fluorine at 77 K.  $^{222}\text{Rn}$ , owing to its intense  $\alpha$ -radiation, produces large numbers of ions and excited atoms. Therefore, for fixation of radon as the fluoride it is necessary to mix a millicurie or larger amounts of the element with gaseous or liquid fluorine in a small volume (25–50 cm<sup>3</sup>) and let the mixture stand for 0.5 h. Radon behaves as activator and reactant. In this way,  $\text{RnF}_2$  is produced.

The first ionization potential of radon (10.7 eV) is smaller than the first ionization potential of xenon, and therefore similar reactions are expected. Thus radon reacts with a number of oxidizing cations such as  $\text{ClF}_2^+$ ,  $\text{BrF}_2^+$ ,  $\text{BrF}_4^+$ ,  $\text{O}_2^+$ ,  $\text{N}_2\text{F}^+$ ,  $\text{N}_2\text{F}_3^+$ ,  $\text{IF}_6^+$ , and so on, and it is believed that it forms  $\text{RnF}^+$  salts. Radon also reacts to some extent with compounds that contain oxidizing anions such as  $\text{ClF}_4^-$ ,  $\text{BrF}_4^-$ , and  $\text{BrF}_6^-$ .

Stable solutions of  $\text{RnF}_2$  have been prepared through spontaneous reactions of  $^{222}\text{Rn}$  with liquid  $\text{ClF}$ ,  $\text{ClF}_3$ ,  $\text{ClF}_5$ ,  $\text{BrF}_3$ ,  $\text{BrF}_5$ , and  $\text{IF}_7$  at 298 K or lower temperatures.

$\text{RnF}_2$  is hydrolyzed by water in a reaction analogous to the reactions of  $\text{KrF}_2$  and  $\text{XeF}_2$  with water. Higher-valent xenon compounds, such as  $\text{XeF}_4$  and  $\text{XeF}_6$ , yield soluble oxygenated xenon species ( $\text{XeO}_3$  and  $\text{XeO}_6^{4-}$ ) on hydrolysis with solutions of appropriate acidity. No corresponding radon species have been observed after hydrolysis of simple or complex radon fluorides. In all cases, only gaseous radon was obtained. Reported preparations of  $\text{RnF}_4$  and  $\text{RnF}_6$  and, by hydrolysis, also  $\text{RnO}_3$  have not been sustained. Because of the chemical similarity of radon with xenon and its lower first ionization potential, a number of other compounds such as  $\text{RnF}_4$ ,  $\text{RnF}_6$ ,  $\text{RnCl}_2$ ,  $\text{RnCl}_4$ ,  $\text{RnO}$ ,  $\text{RnO}_2$ ,  $\text{RnO}_3$ , and  $\text{RnOF}_4$  might be expected. The characterization of these compounds is very difficult because of their radioactivity, decay, short-lived isotopes, and so on. So far, no complex compounds of  $\text{RnF}^+$ ,  $\text{Rn}_2\text{F}_3^+$ , or  $\text{Rn}^{2+}$  have been fully characterized.

## 8 THE CHEMISTRY OF THE LIGHTER NOBLE GASES

The first ionization potentials of the lighter noble gases Ar (15.76 eV), Ne (21.56 eV), and He (24.59 eV) show that these gases will remain difficult to incorporate into compounds. Nevertheless, the first stable neutral argon compound,  $\text{HArF}$ , has been isolated in a solid argon matrix, characterized by IR, and analyzed by ab initio calculations.<sup>63</sup> The calculations indicate that the compound is 'intrinsically stable' with ionic and covalent contributions to the bonding. Furthermore, a wide range of helium compounds,  $[\text{XBeHe}]^+$  (where  $\text{X} = \text{NH}_2$ ,  $\text{CH}_3$ ,  $\text{Ph}$ , etc.) are calculated to be thermodynamically stable.<sup>4</sup> This is likely due to the presence of the covalency-inducing beryllium cation.

## 9 EXPLOSION HAZARDS WITH NOBLE GAS COMPOUNDS

Some noble gas compounds are explosive, so special care should be taken during their manipulation. The most dangerous is  $\text{XeO}_3$ , which can be obtained from  $\text{XeF}_4$ ,  $\text{XeF}_6$ , any  $\text{XeF}_3^+$  or  $\text{XeF}_5^+$  salts when moisture is present, or by the reaction between  $\text{XeF}_6$  and oxides.  $\text{XeO}_3$  is comparable in detonation sensitivity to nitrogen triiodide and in explosive force to TNT. Detonation may be induced by mild heating, by mild mechanical disturbance, by pouring, or may take place spontaneously.

Beside  $\text{XeO}_3$  and  $\text{XeO}_4$ , some xenon oxyfluorides are also thermally unstable compounds. They may detonate, particularly at higher temperatures. Other derivatives of the xenon and krypton fluorides involving ligands less electronegative than fluorine should also be assumed to be of low thermodynamic stability. Many derivatives such as perchlorates and trifluoroacetates are known to be explosive.

## 10 BONDING IN NOBLE GAS COMPOUNDS

For xenon fluorides and oxides, for example, the same models can be applied as for interhalogen and halogen oxy species. Furthermore, the very successful valence shell electron pair repulsion (VSEPR) rules<sup>73</sup> for molecule and ion shapes are as effective for noble gas compounds and their relatives as for classical 'octet' compounds.

All acceptable theories should account for the following facts: only the heavier, more readily ionizable noble gases form compounds and only the most electronegative atoms or groups are satisfactory ligands for the noble gases. Two theories of bonding in noble gas compounds are discussed here (see also *Molecular Orbital Theory* and *Valence Shell Electron Pair Repulsion Model*).

## 10.1 Molecular Orbital Theory

This model does not involve the outer, or higher valence shell orbitals of the noble gas atom, at least not to an extent that could significantly affect the bond energy. The xenon atom orbitals of prime importance are 5p, and less importantly 5s, and for fluorine 2p. It is interesting that Pimentel's<sup>74</sup> bonding model of 1951 for trihalide ions can be extended to the noble gas dihalides without modification. In this case, we have three three-center MOs generated from the Xe 5p<sub>x</sub> and two fluorine 2p<sub>x</sub> orbitals. The best net bonding for the three atoms occurs when the arrangement is centrosymmetric. The molecular symmetry of XeF<sub>2</sub> (*D*<sub>∞h</sub>) is in agreement with this requirement. The xenon atom contributes two electrons and each fluorine ligand one electron to this σp molecular orbital (MO) system. Two electrons are in the bonding MO and two in the nonbonding MO. The antibonding MO is empty. The xenon does not contribute to the nonbonding orbital; therefore the electrons of this orbital are concentrated on the fluorine ligands, thus restoring the fluorine ligand electron density. The bonding electron pair is responsible for binding together all three atoms. Delocalization of the electron pairs of this orbital results in a net negative charge on each fluorine ligand and a positive charge on the Xe atom. The charge distribution is close to the representation F<sup>0.5-</sup>-Xe<sup>1+</sup>-F<sup>0.5-</sup>. This representation fits most of the physical and chemical properties of XeF<sub>2</sub>.

Bonding in XeF<sub>4</sub> can be described in a similar way, having two such three-center systems at right angles. This simple three-center four-electron MO approach is in accord with the near equality of mean thermochemical bond energy in the three xenon fluorides and with the greater bond energy in XeF<sup>+</sup>, but it predicts XeF<sub>6</sub> to be octahedral, which it is not.

## 10.2 Valence Shell Electron Pair Repulsion Theory

This theory implies outer orbital involvement in the bonding. It assumes that each bond between the ligand and the central atom involves an electron pair. A double bond involves four electrons. Further, it assumes that all nonbonding valence electrons have a steric effect. These lone pairs repel other electron pairs more than do bonding electron pairs and have about the same steric requirements as a double bond. Gillespie<sup>75</sup> predicted the shape of unknown species using this theory; all later isolated species conformed to his predictions.

The three-center, four-electron MO approach is as successful as the VSEPR approach for less than six coordination. The VSEPR correctly predicted that XeF<sub>6</sub> should be nonoctahedral and applies straightforwardly to seven and higher coordination numbers, in a way that the simple MO theories cannot.

## 11 RECENT DEVELOPMENTS IN TRANSITION METAL DERIVATIVES

Beyond the relatively simple transition metal salts described previously, many more interesting and esoteric compounds have been discovered in combinations of the noble gases with the transition metals. The broad range of these exciting new compounds warrants a separate in-depth review, so only representative examples will be provided here. Matrix isolation has been used to create the new class of organometallic compounds, M(CO)<sub>x</sub>Ng where Ar and Xe act as weakly bound ligands.<sup>76</sup> Another emerging class of compounds are of formula NgMX, (Ng = Ar or Kr, M = Cu, Ag, Au, X = F, Cl, Br), prepared by laser ablation of the metal followed by reaction with the noble gas and halide source.<sup>77</sup> In these linear compounds, the Ng-M bonds are short and range from 2.3 Å for Ar-Cu to 2.7 Å for Kr-Ag. Theoretical calculations have been used to predict the bond lengths of the compounds for which no experimental data is available.<sup>78</sup> The laser ablation of uranium with CO in the presence of Ar, Kr, and Xe lead to the formation of the compounds, (C)U(O)(Ng), which have been characterized by IR spectra and CO and Ng isotopic substitution.<sup>79</sup> The compound, [AuXe<sub>4</sub>]<sup>2+</sup> 2[Sb<sub>2</sub>F<sub>11</sub>]<sup>-</sup>, was discovered in a study aimed at creating AuF.<sup>80</sup> In the crystal structure, the cation forms a regular square, with Au-Xe bond lengths ~2.7 Å. This compound is a clear indication of the remarkable discoveries waiting to be made in combinations of the noble gases with transition metals.

## 12 APPLICATIONS

In addition to the synthetic uses mentioned previously, such as in oxidizing<sup>81</sup> and fluorinating agents, the noble gases and their compounds have a very broad, and growing, range of applications. With two NMR-active nuclei, <sup>129</sup>Xe and <sup>131</sup>Xe, xenon has found increasing use as an indirect structural probe in a broad range of substances.<sup>82-86</sup> Xenon has been found to prevent hypoxia-induced neuronal damage.<sup>87</sup> Additionally, it has been proposed as a replacement for nitrous oxide, once an economic means of providing the gas is found.<sup>88</sup> Dating methods are being developed using 20Ne/22Ne ratios<sup>89</sup> and the fractional yield of <sup>136</sup>Xe produced by the spontaneous fission of <sup>238</sup>U.<sup>90</sup> Jets of Ne and Ar are used to help tokamak nuclear reactors run more efficiently.<sup>91</sup>

## Glossary

*Critical cooling rate,  $R_c$ :* minimum quenching rate of a melt that results in a glassy product

*Glass transition temperature,  $T_g$ :* temperature at which the viscosity of a glass begins to decrease continuously

*Optical attenuation:* continuous decrease of light intensity when propagating in a glass

---

## 1 THE GLASSY STATE

### 1.1 Introduction

Solids originating from the three-dimensional regular repetition of an elementary cell are described as crystalline. This situation can lead to poorly crystalline solids when the final size of the crystal is very small. This is the case for fine grain materials having nanometer or submicron dimension sizes, often called amorphous because the coherently X-ray diffracting domains are very small. Crystals can also be grown to centimeter size, for example, for jewelry or optoelectronics applications. In both cases, those solids have reached their thermodynamic equilibrium. In contrast, there is a limited but important class of materials that, when prepared from the melt, have no time to arrange and to connect periodically when crossing the strategic liquidus to solidus line. Solids that are obtained in this way are not in equilibrium. They are regarded as frozen liquids because they retain the structure of this disordered state. The corresponding materials are then in the ‘glassy’ or ‘vitreous’ state.

The metastable solids discussed in this article will correspond to this definition; the word glass is preferred to noncrystalline solids that have a connotation that is too

negative and inexact. It must also be appreciated that this state of matter suffers in that it is without a clear descriptive image as is possible, for example, for the crystalline state. Nevertheless, vitreous materials research has become an increasingly active field since the emergence of high technology applications of glasses; examples are fiber optics for telecommunication and medicine, glass lasers, sophisticated optics for telescopes and ophthalmology, and sunglasses.

### 1.2 Conditions of Glass Formation

Noncrystalline solids formation needs to be clarified by reference to the nature of the final product. Several methods lead to amorphous fine particles, for instance, in solution by controlled precipitation. Through gel formation, poorly crystalline  $\text{TiO}_2$  can be obtained according to the process  $\text{Ti}(\text{OR})_4 + \text{H}_2\text{O} \rightarrow \text{Ti}(\text{OH})_4 \text{ gel} \rightarrow \text{amorphous TiO}_2 + \text{H}_2\text{O}$ . In this case, the compound obtained is thermodynamically stable, as when amorphous films are obtained by chemical vapor deposition, sputtering, flash evaporation, and so on.

The noncrystalline solids described here are amorphous and metastable. This specific thermodynamic property is because they all originate from the liquid state. The corresponding glassy or vitreous materials are not very common in solid-state chemistry, and only a limited number of molten salts or molten alloys have the characteristics necessary to produce glasses when cooling.

The formation of glass is a kinetically controlled phenomenon and is directly associated with atomic or ionic diffusion within the melt. This controls the formation and growth of microcrystals when the temperature of the liquid reaches the solidus line (i.e. the crystallization temperature).

Some melts show unexpectedly high viscosities, indicating a large degree of association within this disordered state. This is due to the formation of strong chemical bonds in the liquid, leading to polymerized forms where individual atoms are no longer free to move. The effect of thermal agitation is to maintain the disordered state by bending or rotating the bonds linking the different building elements. Cooling the melt results in an increase of the viscosity and makes the formation of individual small crystallites difficult, owing to poor atomic diffusion. Finally, the melt becomes sufficiently viscous that a point is reached where it has to be considered as a solid, but retains the structure of the mother melt. Such a metastable solid is a glass.

Glass formation or the absence of crystallite nucleation and growth is also dependent on the ‘confusion principle’. This is an empirical observation which suggests that, in a multicomponent melt, several crystalline forms are in competition in the crystallization process; the confused situation that results acts as a barrier to microcrystal growth and enhances the formation of the vitreous state.

Although glasses have been known for more than 4000 years, the number of chemical combinations leading to stable vitreous solids is very limited. In addition, most glasses

have a poor behavior towards devitrification and humidity corrosion and are not suitable for industrial applications.

The most interesting glass compositions are derived from the elements of groups 6 and 7 of the periodic table, that is, the oxides, chalcogenides, and halides. A very specific class of vitreous materials is represented by a new family of noncrystalline solids, the so-called 'metglasses' or metallic glasses; their production is special in the sense that they require very rapid quenching of an alloy melt.

In the oxide family of glasses, the situation is largely dominated by silica ( $\text{SiO}_2$ ); however, the oxides  $\text{P}_2\text{O}_5$ ,  $\text{B}_2\text{O}_3$ ,  $\text{Al}_2\text{O}_3$ , and so on are also known to generate vitreous phosphates, borates, and aluminates. Commercial glasses as used in everyday applications always have complex compositions involving several of these oxides.

The general feature of all chemical combinations that give rise to glass formation is that they correspond to a composition very close to the eutectic region, leading to a liquidus with a low-melting point.

### 1.3 Glass: A Very Special Solid

As previously mentioned, a glass is a liquid which has reached an infinite viscosity without crystallizing. In this sense, this solid is out of equilibrium and will have very specific and unique properties.

In optics, for instance, a glass is an ideal medium for photon propagation. This is because glass is a homogeneous solid without grains and grain boundaries, so that the scattering of light is minimized. For telecommunications, optical fiber technology has been developed to such a degree that the  $\text{SiO}_2$  glasses used can propagate light for more than a hundred kilometers with weak attenuation.

The thermal behavior of a glassy solid is also unique in the sense that all the glasses are characterized by their so-called glass transition temperature,  $T_g$ . Above  $T_g$  a glass cannot be considered as a real solid with infinite viscosity. The relaxation phenomena happening at  $T_g$  correspond to an abrupt change in the viscosity  $\eta$ . This decreases linearly with temperature from  $T_g$  where  $\eta$  is typically  $10^{13}$  P. From this point, the glass becomes a plastic solid that possesses unique properties, allowing shaping such as glass blowing, fiber drawing, and so on. The composition of a glass is often characterized by the softening temperature  $T_s$ , which corresponds to a viscosity of about  $10^7$  P, while the drawing temperature for optical fiber preparation corresponds to a viscosity close to  $10^5$  P.

Another property, characteristic of glassy materials, takes place above  $T_g$  when individual atoms begin to have a certain mobility owing to the decrease in viscosity and increase in thermal agitation. From this point, the solid tends towards its thermodynamic equilibrium by generating ordered crystalline phases; this is the domain of microcrystallite nucleation and crystal growth. The control of this phenomenon is essential in glass technology: devitrification can be detrimental, in optics for instance, because this generates scattering centers that are a

major cause of optical loss. In other cases, the precise control of microcrystallization leads to very interesting composite materials, the vitroceramics, which consist of a glassy matrix in which submicronic crystals of consistent size are nucleated. The Vision range of cookware developed by Corning is a good example of this kind of product, characterized by an acceptable transparency in the visible region together with a high resistance to thermal shock. In this application, the presence of microparticles is also beneficial in decreasing and attenuating the propagation of mechanical and thermal phonons. The control of glass ceramics preparation at an industrial scale is a difficult challenge, especially when additional nucleating agents such as nanosize  $\text{ZrO}_2$  have to be dispersed inside the silica-based matrix. This has been accomplished by Schott with the development of the Zerodur glass ceramic that is insensitive to temperature and is used as substrate for the very large mirrors of the astronomical telescopes. Recently complex silicate compositions containing a significant amount of rare earth and fluorine have been investigated with the aim of taking advantage of a glassy matrix containing low phonon RE doped fluorides crystallites, for laser or optical amplification.<sup>1</sup>

The glass-crystal competition, which is a permanent phenomenon in glass technology, is illustrated in Figure 1 by a typical thermal analysis, recorded for a fluoride glass.

More complex phenomena can also occur, especially when the glass is prepared from complex melt compositions containing several glass-forming components. In this event, subliquidus immiscibility is possible, giving rise to phase separation between two interconnecting glass frameworks usually of very different chemical compositions. One of them can be leached, for example, while the other forms a 3-D porous skeleton. The Vycor® glass developed by Corning is based on this phenomenon. As a frozen liquid, the vitreous state is a unique, homogeneous medium for light transmission. The absence of scattering loss due to grains, grains boundaries,

**Figure 1** Thermal analysis of a fluoride glass showing characteristic temperatures:  $T_g$  is the glass transition temperature;  $T_x$  corresponds to the beginning of the crystallization;  $T_m$  is where the crystalline phase starts to melt;  $T_l$  is the liquidus temperature corresponding to the end of the melting process

the easy shaping above  $T_g$  explains why glass is a dominating materials for windows, bottles, optical fibers, and so on.

## 2 OXIDE GLASSES

### 2.1 Glass Formation in Oxide Systems

Oxide glass is one of the oldest materials made by man and vitreous objects are associated with the oldest civilizations. Halfway between art and technology, the development of glass making has been for many centuries essentially empirical. Most glasses have been of the soda-lime-silica type,  $\text{SiO}_2$  being the major component. The conditions of glass formation in  $\text{SiO}_2$ -based systems have been extensively investigated and the generally recognized key factors are (1) formation of a 3-D aperiodic framework of  $\text{SiO}_4$  tetrahedra sharing corners, (2) thermal motion easily causing rotation or bending of the strong Si–O–Si covalent bond leading to lack of periodicity, and (3) the skeleton can also be a giant negative anion if glass modifier oxides, such as  $\text{Na}_2\text{O}$ ,  $\text{CaO}$ , and so on, are combined with  $\text{SiO}_2$ . In the latter case, the  $\text{SiO}_4$  unit can contain two kinds of oxygen environment: bridging and covalently connected with two Si atoms; nonbridging, bonded on one side to Si atoms and having an ionic interaction on the other side, with the alkali ions statistically distributed inside the framework. Figure 2 illustrates a two-dimensional representation of a  $\text{SiO}_2$ -based glass.

The same type of strong covalent network with a large degree of freedom between the connected units is also found in a few other glass-forming oxides such as  $\text{B}_2\text{O}_3$ ,  $\text{P}_2\text{O}_5$ ,  $\text{As}_2\text{O}_3$ ,  $\text{GeO}_2$ , and so on. The vitreous oxides strongly dominate glass science because they offer a large variety of materials

**Figure 2** Structural representation of a  $\text{SiO}_2$ -based glass. The giant 3-D aperiodic skeleton is formed by  $\text{SiO}_4$  tetrahedra sharing corners. The addition of glass modifier oxides such as  $\text{PbO}$ ,  $\text{Na}_2\text{O}$ , and  $\text{CaO}$  results in nonbridging oxygen atom sites and a statistical distribution of the cations  $\text{Pb}^{2+}$ ,  $\text{Na}^+$ , or  $\text{Ca}^{2+}$  throughout the lattice

with good thermomechanical properties, high resistance to devitrification, and good chemical durability.

### 2.2 Vitreous Silica and Silicate Glasses

#### 2.2.1 Vitreous Silica

Silica glass,  $\text{SiO}_2$ , was initially prepared by fusion of natural crystalline  $\text{SiO}_2$ , such as quartz or sand. At temperatures above  $1750^\circ\text{C}$  the melt is viscous enough to prevent any crystallization upon cooling. Much purer material, made to meet the requirements of optical fiber technology (e.g. ultralow-loss waveguides) is produced by the vapor phase oxidation<sup>2</sup> of ultrapure  $\text{SiCl}_4$ , following the reaction  $\text{SiCl}_4 + \text{O}_2 \rightarrow \text{SiO}_2 + 2\text{Cl}_2$ . The recent structural information obtained by Elliot<sup>3</sup> and Wright<sup>4</sup> confirms the initial model of Warren.<sup>5</sup> The basic unit of the framework is a very regular tetrahedron with an Si–O bond of  $1.608\text{ \AA}$  and an O–Si–O angle of  $109.7^\circ$ . Instead of being collinearly connected, the tetrahedra form a spectrum of intertetrahedral angles distributed around the average value of Si–O–Si  $\sim 150^\circ$ . With a very low thermal expansion coefficient ( $\alpha = 5 \times 10^{-7}^\circ\text{C}^{-1}$ ),  $\text{SiO}_2$  glass shows a strong resistance to thermal shock. On the other hand, with a  $T_g$  close to  $1200^\circ\text{C}$ , this glass necessitates a very high temperature ( $>1700^\circ\text{C}$ ) for blowing or fiber drawing. However, silica is highly resistant to devitrification, so that shaping and fiber drawing at such high temperature do not induce any crystallization. Silica is also highly resistant to corrosion, which makes this glass of large interest for long-term applications such as in optical fiber telecommunications.

As far as optical properties are concerned, vitreous silica is highly transparent from nearly  $160\text{ nm}$  ( $8\text{ eV}$ ) in the UV to  $3\text{ }\mu\text{m}$  in the infrared (IR), as shown in Figure 3.

In the fiber form, silica exhibits a minimum optical loss of nearly  $0.2\text{ dB km}^{-1}$  at  $1.55\text{ }\mu\text{m}$ , that is far away from the UV and IR absorption edges. Attaining such a low attenuation is possible because of the use of the modified chemical vapor deposition (MCVD) process that eliminates metallic impurities during preform preparation. The usable transmission range of silica fibers utilized in telecommunications is typically from  $1.3\text{ }\mu\text{m}$  to  $1.6\text{ }\mu\text{m}$  as shown in the attenuation curve in Figure 4. In that range, the remaining losses are due to intrinsic factors: Rayleigh scattering combined with multiphonon absorption, and to extrinsic absorption due to the presence of residual hydroxyl OH groups responsible for the band at  $1400\text{ nm}$ . This band corresponds actually to the first overtone of the fundamental O–H vibration. (see also Section 4.3.1)

The typical constitution of an optical fiber is shown in Figure 5. Determined by the initial preform geometry, the core diameter is a few micrometers while the cladding is  $\approx 125\text{ }\mu\text{m}$ . The overall diameter for coated fibers is around  $250\text{ }\mu\text{m}$ . With core diameters of the order of magnitude of the propagating wavelength, only the fundamental mode is

**Figure 3** Optical transmission spectra of silica and nonoxide glasses. ZBLAN glass composition is given in Figure 12

**Figure 4** Optical attenuation curve of a single-mode commercial silica fiber

guided in fibers, which are then designated as single-mode fibers.

Because of basic optical principles, the light injected into the fiber must belong to a geometrical acceptance cone in order to be guided within the core. This condition is given by the numerical aperture, defined as  $NA = \sin \theta_m = (n_1^2 - n_2^2)^{1/2}$  with  $\theta_m$ , the maximum angle of the cone, and  $n_1$  and  $n_2$  the refractive indices of the core and cladding, respectively. Numerical apertures are usually between 0.1 and 0.3 for telecommunication applications, with the refractive index of pure silica equal to 1.4586 at sodium D-line.

For further reading and references on the preparation of silica preforms and fibers, on light propagation and optical losses in fibers, see Ref. 6.

Recently, large-scale research has been devoted to a novel type of silica optical fiber, named photonic crystal fiber, whose structure is very different from that of the conventional fiber described above. The cross section of a photonic crystal fiber is shown in Figure 6. The cladding is made of glass with periodic air holes surrounding a full glass-core. This results in a cladding region with average refractive index lower than that

of the core, and light can propagate by total internal reflection, like in a conventional fiber. Among other advantages, photonic crystal fibers possess the potential for broad-band single-mode guiding and high nonlinearities. Further reading is available in Ref. 7

### 2.2.2 Alkali and Other Binary Silicate Glasses

Glasses can be made in all the alkali silicate systems over a range of composition, from  $\text{SiO}_2$  itself up to about 30 mol %  $\text{Li}_2\text{O}$ , 50 mol %  $\text{Na}_2\text{O}$ , or 50 mol %  $\text{K}_2\text{O}$ . The first observation is a large drop in the liquidus temperature and a drastic modification of some properties. For example,  $T_g$  falls from 1200 °C for  $\text{SiO}_2$  to 350 °C for the 45%  $\text{Na}_2\text{O}$ -containing glass. Over the same composition range the thermal expansion increases almost linearly, from  $\alpha = 5 \times 10^{-7} \text{ }^\circ\text{C}^{-1}$  to  $\alpha = 200 \times 10^{-7} \text{ }^\circ\text{C}^{-1}$ . For comparison, a typical commercial container glass has an  $\alpha$  of  $90 \times 10^{-7} \text{ }^\circ\text{C}^{-1}$  and a  $T_g$  around 520 °C. The second tendency of alkali silicate glasses is to give rise to subliquidus immiscibility, leading to glass-phase separation; the same materials are also sensitive to moisture and water corrosion, especially in the alkali-rich region.

In most of the other binary silicate systems, involving oxides such as  $\text{BaO}$ ,  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{Al}_2\text{O}_3$ , and so on, the liquidus temperature is very high and glass formation is limited by immiscibility in the melt; rapid quenching is needed to obtain glasses. The  $\text{SiO}_2$ – $\text{PbO}$  system is of particular interest because of the low liquidus temperatures; these render glass formation easier and lead to heavy glasses due to the high atomic weight of lead.

The alkali silicate glasses are easily corroded by aqueous acids and the main reaction is an exchange between  $\text{H}_3\text{O}^+$  of the solution with the alkali  $\text{M}^+$  of the glass; the corrosion rate increases with the ionic radii of  $\text{M}^+$ , that is,  $\text{K}^+ > \text{Na}^+ > \text{Li}^+$ . The chemical durability is greatly increased by addition of divalent  $\text{CaO}$  or trivalent  $\text{Al}_2\text{O}_3$  oxides, leading to commercial soda-lime–silica compositions.

The presence of modifier ions in silicate glasses make it possible to create optical guiding structure by ion exchange at

**Figure 5** Typical structure of a silica fiber for telecommunication. Frame: Principle of light propagation in a multimode optical fiber

**Figure 6** Cross section of a photonic crystal fiber

the glass surface. For example,  $\text{Na}^+$  ions in the glass can be exchanged for more polarizable ions like  $\text{Cs}^+$ ,  $\text{Rb}^+$ ,  $\text{K}^+$ , or for small ions like  $\text{Li}^+$  that generates collapsing and consequent densification of the glass matrix. Higher polarizability or material densification result in an increase of the refractive index.<sup>8</sup>

### 2.2.3 Commercial $\text{SiO}_2$ -based Glasses

Commercial glass compositions change from one manufacturer to another, even for a given product. The selection given in Table 1 is taken from the article by Rawson<sup>9</sup> and indicates the general tendency in composition for a given application.

Glasses 1, 2, and 3 are, respectively, float glass for windows, container glass such as for bottles, and the glass used to make incandescent lamp bulbs. They have been optimized to achieve the viscosity–temperature characteristics required by the shaping process, and they are low cost. Glasses 4 and 5 are very rich in  $\text{PbO}$  and correspond to the traditional lead crystal composition having a high refractive index,  $n = 1.6$ , giving a brilliant appearance when cut. Glass 5 has the highest content of  $\text{PbO}$  and has a value of  $n = 1.85$ . These glasses are also strongly absorbing towards X ray and  $\gamma$  radiation.

Glasses 6, 7, and 8 represent the large and important group of borosilicate glasses including Pyrex, used for chemical apparatus and domestic cookwares.

Glass 9 is rich in alumina ( $\text{Al}_2\text{O}_3$ ) and is a high-melting material suitable for glass fibers as used in composite reinforcement or thermal isolation. Glass 10 is used for cathode-ray tubes, glass 11 is an optical glass, and glass 12 is a solder glass used because of its high fluidity at about  $550^\circ\text{C}$  to seal soda-lime glasses.

## 2.3 Boric Oxide and Borate Glasses

### 2.3.1 Boric Oxide Glass

$\text{B}_2\text{O}_3$  is very easily contaminated by  $\text{OH}$  and this significantly affects thermal properties, such as the melting point around  $450^\circ\text{C}$ , leading to a melt with a rather low viscosity which vitrifies easily; the corresponding glass has a  $T_g$  close to  $260^\circ\text{C}$ .

The building units in  $\text{B}_2\text{O}_3$  glasses are triangular, owing to the three bonding electrons on the boron atom and  $\text{sp}^2$  hybridization. Their association by corner sharing leads to a 2-D aperiodic network. As shown in Figure 7, the interchain connections generate boroxol groups,  $\text{B}_3\text{O}_3\text{O}_{3/2}$ .

### 2.3.2 Borate Glasses

Glass formation in the alkali borate system is characterized by an increase in the liquidus temperature, a high tendency to crystallize compared to  $\text{B}_2\text{O}_3$  itself, and to give subliquidus immiscibility.<sup>10,11</sup> The phase separation phenomena can markedly affect the properties of borate glasses such as viscosity. The origin of this immiscibility can be found in the formation of two independent glassy networks during the addition of alkali oxides,  $\text{M}_2\text{O}$ .<sup>12</sup> The additional oxygen atoms brought by  $\text{M}_2\text{O}$  lead to a  $\text{BO}_4$  tetrahedra-based

**Table 1** Composition of some commercial glasses<sup>a</sup>

<sup>a</sup>In wt %.**Figure 7** Structural representation of boron oxide (B<sub>2</sub>O<sub>3</sub>) glass. The giant 2-D skeleton is formed by BO<sub>3</sub> triangles sharing corners. Specific B<sub>3</sub>O<sub>3</sub>O<sub>3/2</sub> boroxol groups can be present in the structure

framework which is separated from the initial BO<sub>3</sub> triangular-based structure.

### 2.3.3 Borosilicate Glasses

While the practical applications of borate glasses are very limited, the glasses derived from Na<sub>2</sub>O–B<sub>2</sub>O<sub>3</sub>–SiO<sub>2</sub> systems are of considerable technological importance. They include the glass commonly known as Pyrex, used for chemical apparatus and ovenware.

The addition of B<sub>2</sub>O<sub>3</sub> to a silicate glass markedly reduces the thermal expansion coefficient and consequently enhances the resistance to thermal shock. At the same time, the chemical durability, especially the resistance to acid attack, is greatly improved.

Several borosilicate glass compositions exhibit immiscibility; they separate into two interconnecting phases, one rich in

sodium borates, the other being almost pure silica. The first phase can be leached out by immersing the material in acid. The densified remaining glassy phase gives so-called Vycor<sup>®</sup> glass. The porous silica skeleton can also be used as a host for enzymatic and catalytic reactions.

## 2.4 Phosphate Glasses

The higher phosphorus oxide, P<sub>2</sub>O<sub>5</sub>, is a highly hygroscopic material. On melting it gives a very viscous liquid which can be readily supercooled to give a glass. This particular material has no practical interest owing to its rapid corrosion by water and moisture.

Information on binary phosphate glasses has to be regarded with some care owing to the variable amount of water retained in the glass and which varies with composition, time, and temperature of melting. The glass-forming ability and properties are very dependent on OH content, which introduces strong hydrogen bonds and which varies according to the equilibrium  $2\text{OH}^- \rightleftharpoons \text{O}^{2-} + \text{H}_2\text{O}$ .

The most interesting phosphate glasses for practical applications are multicomponent materials, often containing fluorides. They have been developed as optical glasses for laser applications; for instance, the Nd<sup>3+</sup>-doped phosphate glasses of high optical quality used in large, high-power laser fusion have been selected because of their low nonlinear refractive index which attenuates the risk of beam self-focusing.

Er<sup>3+</sup>-doped phosphate glasses are also very efficient lasers operating at 1.54 μm. In order to improve the resistance of the material to thermal shocks due to intense light pumping, phosphate glasses can be chemically strengthened by an ion-exchange process – Na<sup>+</sup> or K<sup>+</sup> for Li<sup>+</sup> – at the glass surface. Thus, laser output as high as 600 mJ at 1.54 μm could be achieved with 100 J pump energy.<sup>13</sup>

It must be noticed that Ca rich phosphate glasses and glass ceramics having a composition very close to apatite, the main component of bones are bioactive materials capable of bonding to natural bones and then used for surgery implantation.<sup>14</sup>

## 2.5 Miscellaneous Oxide Glasses

Several other oxides, such as  $\text{GeO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{TeO}_2$ , and  $\text{V}_2\text{O}_5$ , containing small highly charged polarizing cations, are also able to form glasses when undercooling the melt. In these cases, the tendency for crystal formation upon cooling is very high and fast quenching is necessary.

$\text{GeO}_2$  is used in small quantities in the core of optical fibers for increasing the refractive index of  $\text{SiO}_2$  in order to achieve the optical guiding conditions.

The only interest in this expensive oxide is its better IR transparency owing to a shift of the multiphonon edge; glasses of optical quality are therefore difficult to achieve even in multicomponent compositions. Addition of modified oxides such as alkali to  $\text{GeO}_2$  contributes to the formation of  $\text{GeO}_6$  octahedra in addition to the existing  $\text{GeO}_4$  tetrahedra. Lead germanate glasses are commercial IR products.

The situation is very similar for  $\text{Al}_2\text{O}_3$ -based glasses. In the  $\text{Al}_2\text{O}_3$ - $\text{CaO}$  system, where the two starting components have high-melting points, glasses can be prepared by fast quenching of the melt in the eutectic regions where the liquidus is around  $1400^\circ\text{C}$ . The stability of  $\text{Al}_2\text{O}_3$ -based glasses is improved by making the composition more complex, but  $\text{SiO}_2$  addition is detrimental to IR transparency.

A homogeneous  $\text{TeO}_2$  glass is obtained only by quenching the melt when it is viscous above the melting point. The most stable tellurite glasses are formed in systems such as  $\text{TeO}_2$ - $\text{PbO}$ ,  $\text{BaO}$ , and so on. These glasses are of some interest because of their high refractive index, which can reach values up to 2.3. As far as phonon energies are concerned, tellurites are classified as intermediate glasses, between silicates and halides.<sup>15</sup>

$\text{V}_2\text{O}_5$  melts at  $660^\circ\text{C}$  and forms a glass only by fast quenching. Therefore complex compositions belonging to the system  $\text{V}_2\text{O}_5$ - $\text{BaO}$ - $\text{K}_2\text{O}$ - $\text{ZnO}$  enhance glass-forming ability. The most notable characteristic of these glasses is due to the easy mixed valence  $\text{V}^{4+}/\text{V}^{5+}$  situation, leading to semiconducting properties and coloration arising from charge transfer absorption.

The rigidity of the silicate or phosphate glass network can be markedly enhanced by substituting some oxygen atoms by nitrogen. The corresponding oxynitride glasses are characterized by a general modification of their thermal properties such as a sharp decrease in the expansion coefficient  $\alpha$  and an increase in glass transition temperature. In the  $\text{Y-Si-Al-O-N}$  system,<sup>16</sup> when the nitrogen atomic percentage is increased from 0 to 6%,  $\alpha$  varies from  $70 \times 10^{-7}$  to  $35 \times 10^{-7}^\circ\text{C}^{-1}$  and  $T_g$  moves from  $800$  to  $900^\circ\text{C}$ . Both observations indicate an increase in the degree of cross-linking when the trivalent N atoms substitute the divalent O atoms in the glass-forming skeleton.

The most effective way of making nitrogen-containing silicate glasses is to melt together mixtures of oxides and nitrides in a nitrogen or inert atmosphere. A maximum of 10% atomic substitution is generally attained and it has been observed that the nitrogen solubility is increased if the glass

composition contains  $\text{Al}_2\text{O}_3$ . This is attributed to the fact that the  $\text{Si}(\text{O},\text{N})_4$  and  $\text{AlO}_4$  tetrahedra are of similar size.

## 2.6 Glasses from Ionic Salts

Vitreous materials can be formed by undercooling certain molten salts consisting of mixtures of nitrates, acetates, and sulfates, which contain discrete anions such as  $\text{NO}_3^-$ ,  $\text{C}_2\text{O}_4^{2-}$ ,  $\text{SO}_4^{2-}$ , and so on.

As discussed by Angell,<sup>17</sup> the conditions for glass formation in such unusual systems are not very well understood, especially because of a lack of information about contamination of these molten salt mixtures by water.

As expected, the absence of crystallization upon cooling is especially marked when the melt is close to the eutectic region, having a low liquidus temperature. For example, the region of glass formation in the binary system  $\text{KNO}_3$ - $\text{Ca}(\text{NO}_3)_2$  is for 60 mol %  $\text{KNO}_3$ , corresponding to a eutectic temperature of  $146^\circ\text{C}$ , while the melting points of the two constituents are  $337^\circ\text{C}$  ( $\text{KNO}_3$ ) and  $561^\circ\text{C}$  ( $\text{Ca}(\text{NO}_3)_2$ ).

Several sulfate mixtures such as  $\text{KHSO}_4$ - $\text{NaHSO}_4$  are also glass formers with good resistance to crystallization.

The fact that many crystalline hydrates melt, such as  $\text{Ca}(\text{WO}_3)_2 \cdot 4\text{H}_2\text{O}$ , while more complex binary hydrated systems have a tendency to form glasses is an indication of the critical role of the water molecule and the hydrogen bond.

It is clear that the polymerization process in these low-melting melts involves strong hydrogen bonding between the  $\text{OH}^-$  group and the  $\text{O}^{2-}$  atom of the neighboring anions. Rotation as well as bending of the hydrogen bond is rather easy, making possible a system with a lack of periodicity.

There are no commercial applications for these unconventional glasses.

## 3 CHALCOGENIDE GLASSES

### 3.1 Introduction: Definition

Chalcogenides are compounds containing elements of group 6 of the periodic table, with the exception of oxygen. Chalcogens such as sulfur, selenium, and tellurium are characterized by the typical six-electron outer shell  $s^2p_x^2p_y^1p_z^1$ . In most of the vitreous combinations described in this article, the chalcogen atom will be divalent, using its two odd electrons in twofold coordination. The two remaining nonbonding pairs will be considered as localized lone pairs having a strong stereochemical effect around the chalcogen and introducing nonbonding atomic levels in the energy diagram.

Most of the metallic chalcogenides are found as crystalline materials, often with 2-D character and only a very limited number of them are able to form glasses from the melt.

Consequently, the chalcogenide glass family is essentially represented by polymer-type compounds in which the chemical bond is highly covalent. The chalcogen atom is then bonded to neighboring elements of the periodic table with similar electronegativity, such as As, P, Ge, Si, Cl, Br, and Bi. The conditions of glass formation and the physics of amorphous chalcogenides have been discussed and reviewed by Elliot.<sup>18,19</sup>

These materials are generally semiconductors with small band gaps in the range of 1–3 eV, owing to the specific character of the chemical bonds, that is, covalence plus nonbonding electrons. The band-gap edge is then located in the visible or near-IR region and most of those glasses are black. Owing to the high atomic weights of the constituent elements, these glasses have IR absorption edges located in the long wavelength region, which renders these materials very attractive for IR light transmission.

### 3.1.1 Classification of Chalcogenide Glasses

The noncrystalline chalcogen-containing materials can be distinguished according to the nature of the accompanying elements. As presented in Table 2, four general families of glasses can be identified.

Category 1 is represented by pure chalcogen, solid solutions of different chalcogens, or association with a pseudochalcogen such as As or P having a very similar electronegativity. Crystalline sulfur or selenium on melting give very viscous melts, indicating that the liquid phase is highly polymerized. Since the elemental chalcogens are twofold coordinated, the structural configuration of the resulting polymer is limited to rings or chains bonded together by van der Waals or dipole–dipole forces. A sulfur glass can be made by quenching the melt above a temperature of about 440 K, when the high viscosity is due to long polymeric chains.

In the case of Se, the chains already exist in the crystalline form and, just above the melting point ( $T_m = 490$  K), the liquidus is viscous enough to lead to easy glass formation even with a moderate cooling rate.

Tellurium, which has more metallic character, is not able to support a polymeric arrangement in its liquid phase, which has a low viscosity like a molten metal. Glass formation is only possible from  $\text{Te}_{1-x}\text{Se}_x$  solutions, and even then very fast quenching such as melt spinning is needed.

**Table 2** Categories of chalcogen-based glasses<sup>a</sup>

| No. Category                                        | Examples of glass former                                                                                                |
|-----------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------|
| 1. Pure chalcogen (6–6)<br>or pseudochalcogen (5–6) | S, Se, $\text{Se}_{1-x}\text{Te}_x$<br>$\text{Se}_{1-x}\text{S}_x$ , $\text{As}_2\text{S}_3$ , $\text{As}_2\text{Se}_3$ |
| 2. Semimetallic chalcogenides                       | $\text{SiSe}_2$ , $\text{GeS}_2$                                                                                        |
| 3. Metallic chalcogenides                           | $\text{Al}_2\text{S}_3$ , $\text{Ga}_2\text{S}_3$                                                                       |
| 4. Chalcogen halides                                | $\text{Te-Cl}$ , $\text{Te-Br}$                                                                                         |

<sup>a</sup>5 and 6 represent elements from group 5, except N, or group 6, except O, of the periodic table.

The most interesting materials in this group of glasses are the arsenic sulfide and selenide,  $\text{As}_2\text{S}_3$  and  $\text{As}_2\text{Se}_3$ . This combination of groups 15 and 16 elements gives rise to a very strong covalent 2-D framework, rendering these materials stable to devitrification and chemical attack. Glass formation has also been discovered in the  $\text{P}_{1-x}\text{Se}_x$  system<sup>20</sup> close to  $x = 0.2$  and  $x = 0.75$ , but the corresponding glasses have no application due to poor chemical durability.

Category 2 corresponds to chemical combinations of groups 4 and 6 elements. In this particular case the group 4 atoms, such as Si and Ge, will be fourfold coordinated and form  $\text{SiS}_4$  or  $\text{GeS}_4$  tetrahedra. From this elementary, symmetric module, a 3-D aperiodic framework is expected similar to that in  $\text{SiO}_2$  glass, except that the large size of the tetrahedron will allow edge sharing in addition to corner sharing.

This classification is of course arbitrary, and it must be noted that the very stable chalcogenide glasses are often ternary or quaternary compounds corresponding to mixed complex compositions of categories 1 and 2. For instance, the commercial glass called AMTIR (Amorphous Materials Transmitting Infrared) is the multicomponent glass  $\text{As}_{12}\text{Ge}_{33}\text{Se}_{55}$ . Figure 8 represents the region of glass formation in the system As–Ge–Se.<sup>20</sup>

Category 3 corresponds to combinations of a real metal such as aluminum or gallium with a chalcogen such as S. The simple sulfides,  $\text{Al}_2\text{S}_3$  or  $\text{Ga}_2\text{S}_3$ , cannot form glasses by themselves and need to be combined with glass modifiers such as rare earth sulfides  $\text{La}_2\text{S}_3$ . For some other glasses, stabilizers are also necessary and ternary glasses have been isolated in the system  $\text{Ga}_2\text{S}_3\text{--MnS--La}_2\text{S}_3$ ,<sup>21</sup> for instance. The glass-forming units here are also tetrahedral  $\text{AlS}_4$  or  $\text{GaS}_4$ , and probably octahedral  $\text{MnS}_6$ .

The last group of glasses, corresponding to category 4, are similar to those of class 1 in the sense that they have a Se-type chain structure. A decade ago, glasses were discovered<sup>22</sup> in the Te–X system ( $X = \text{Cl, Br, I}$ ), leading to glassy polymeric materials with very low phonon energies and excellent IR-transmitting properties.

## 3.2 Structure and Bonding in Chalcogenides Glasses

### 3.2.1 The Building Units

For most of the chalcogenides in categories 1–4, three types of building unit (Figure 9) can be distinguished, giving rise to so-called short-range order.

1. The angular unit is illustrated by the Se atom: among the six outer electrons, only two are bonding, the two other pairs being localized and giving, by repulsion with the bonding pairs, a pseudotetrahedral arrangement around Se.
2. The distorted triangular unit observed around group 5 elements such as As: in this case the three bonding

**Figure 8** Glass-forming zone (approximate, since it depends on the quenching rate) in the Ge–Se–As system. The three components Se, GeSe<sub>2</sub>, and As<sub>2</sub>S<sub>3</sub> alone are able to form glasses

**Figure 9** Building units found in most of the chalcogenide glasses: the angular unit existing in Se-type glasses; the pyramidal unit of the As-based glasses; and the tetrahedron of the GeS<sub>2</sub> glass

electrons lead to three bonding pairs which complement the remaining lone pair.

- From the analysis of the corresponding crystalline materials the tetrahedron is the basic unit in the SiS<sub>2</sub>-, GeSe<sub>2</sub>-, Al<sub>2</sub>S<sub>3</sub>-, and Ga<sub>2</sub>S<sub>3</sub>-based glasses. When the glasses are stabilized by modifiers such as Na<sub>2</sub>S, BaS, and La<sub>2</sub>S<sub>3</sub>, the tetrahedra are formed by bridging and nonbridging chalcogen.

### 3.2.2 The Nonperiodic Skeleton of Chalcogen-based Glasses

From the elementary units previously described, several 1-D, 2-D, or 3-D frameworks can be constructed, as shown in Figure 10. One-dimensional chains are found in Se by connecting the angular units. In sulfur, it has been observed

that the unit can be rotated along the covalent  $\sigma$ -bond, giving rise to an equilibrium between chains and S<sub>8</sub> rings. The same situation occurs in SiS<sub>2</sub> glass, but here the chains are formed by connecting SiS<sub>4</sub> tetrahedra by sharing edges. In this SiS<sub>4/2</sub> chain, the distorted Si–S–Si bond reflects the strong stereochemical effect of the S electronic lone pairs.

In both 1-D-based glasses, the interactions between the chains being of the van der Waals type, are weak, and allow easy rotation or bending. Two-dimensional configurations, giving rise to distorted layer structures, are found in As<sub>2</sub>S<sub>3</sub>- or GeS<sub>2</sub>-type glasses. The connection of pyramidal and angular units in As<sub>2</sub>S<sub>3</sub> lead to an infinite distorted 2-D framework. The periodicity in this orpiment-related structure can be easily destroyed because the layers are bonded by van der Waals forces and because rotation and bending are possible around the S–As–S  $\sigma$ -bond without costing too much energy.

In GeS<sub>2</sub>-based glasses, examination of the parent crystalline materials indicates that GeS<sub>2</sub> tetrahedra, connected by corner and edge sharing, also form a layered 2-D structure.

A 3-D framework analogous to the SiO<sub>2</sub> cristobalite structure is of course easy to build from elementary tetrahedra. Notice that, in the Ge/S system, the glass-forming ability is maximum for the composition GeS<sub>4</sub> which corresponds to tetrahedra connected by a S–S pairs bonds.

In all of these giant skeletons, the glassy state arises from the easy lack of periodicity. This means that a small rotation or bending of the bonds does not markedly affect the free enthalpy of the system because of framework flexibility.

**Figure 10** The different frameworks formed in chalcogen-based glasses: (a) a chain-like structure in Se or  $\text{SiS}_2$ ; (b) 2-D skeleton in  $\text{As}_2\text{Se}_3$  formed by linking Se angular and As pyramidal units; (c) by sharing corners and edges, the tetrahedra of the  $\text{GeS}_2$ -based glasses also form a 2-D framework

### 3.3 Properties of Chalcogen-based Glasses

#### 3.3.1 Thermal Properties

The glass transition temperatures give a good indication of the thermal stability of chalcogen-based glasses. Below  $T_g$  the glass is a real solid with infinite viscosity while above  $T_g$  the viscosity begins to decrease linearly, rendering the glass first plastic and then similar to a viscous liquid. Knowledge of these data is essential to allow comment on the thermal capabilities and for shaping the glass. Operations such as annealing, for

**Table 3** Glass transition temperatures for several chalcogen-based glasses

| Glass                                        | $T_g$ ( $^{\circ}\text{C}$ ) |
|----------------------------------------------|------------------------------|
| S                                            | -27                          |
| Se                                           | 35                           |
| $\text{Te}_3\text{Cl}_2$                     | 82                           |
| $\text{As}_2\text{S}_3$                      | 205                          |
| $\text{As}_2\text{Se}_3$                     | 195                          |
| $\text{As}_{12}\text{Ge}_{33}\text{Se}_{55}$ | 362                          |
| $\text{GeSe}_2$                              | 422                          |
| $\text{GeS}_2$                               | 492                          |

relaxing the local stresses, and fibering, for optical waveguide preparation, need a precise determination of  $T_g$ . Table 3 gives  $T_g$  values for several glasses.

The glass transition temperature is directly related to the dimensionality of the glass and can be considered as an indication of the rigidity of the framework. For instance, the low  $T_g$  glasses are 1-D chain-like materials such as Se or  $\text{Te}_3\text{Cl}_2$ , while the high  $T_g$  glasses belong to families having a 2-D or 3-D configuration.

The same situation is found when wrong-bond<sup>23</sup> non-bridging anions are introduced in a glass by way of chalcogen-halogen substitution or sulfides are added as modifiers. For instance,  $T_g$  falls rapidly when  $x\text{S}$  atoms are substituted by  $2x\text{I}$  atoms to preserve electroneutrality in  $\text{GeS}_2$  glass. The result of this substitution, when  $x = 1$ , is the formation of a chain-like glass  $\text{GeSI}_2$ , containing tetrahedral  $\text{GeS}_{2/2}\text{I}_2$  units connected by corners and sharing only S atoms ( $\text{GeS}_{2/2}\text{I}_2$ ), the I atoms being terminal.

When  $\text{Na}_2\text{S}$  is added to  $\text{GeS}_2$  the same phenomenon is observed, the additional S atoms break the dimensionality of the skeleton by the transformation of the bridging bonds  $\cdots\text{Ge}-\text{S}-\text{Ge}\cdots$  into two nonbridging  $\cdots\text{Ge}-\text{S}^--\text{Na}^+\text{S}^--\text{Ge}\cdots$  bonds, as indicated in Figure 9.

Chalcogen-based glasses can be deposited to form thin amorphous films by thermal evaporation or sputtering, owing to their low thermal characteristics. This technique is widely used in the deposition of Se-rich glasses on to cylindrical drums used as the photosensitive surface in Xerography.

#### 3.3.2 Electrical and Optical Properties

A simplified picture of the density of states in a chalcogenide material comprises a low-energy  $\sigma$  valence bond and, at higher energy, the  $\sigma^*$  antibonding level corresponding to the conduction band. The novelty of chalcogen-based glasses comes from the existence of a nonbonding (nb) level arising from the lone pair electrons situated above the  $\sigma$  level, as depicted in Figure 11. The optical band gap  $E_g$  is due to the transition from the nb level to the  $\sigma^*$  level and it is observed that  $E_g$  varies from about 1 to 2.5 eV. The corresponding optical absorption edges follows Urbach-edge behavior and

**Figure 11** Optical band gap in chalcogen-based glasses. The optical band gap  $E_g$  is due to the transition from the nonbonding level to the antibonding level  $\sigma^*$ , which results in black-color glasses

give high values of the absorption coefficient  $\alpha$  in the visible part of the spectrum. Consequently, most of the chalcogen-based glasses are black, as shown in Figure 11 except  $\text{As}_2\text{S}_3$  that has a reddish color. (Recall the relationship  $\lambda_{\text{max}} (\mu\text{m}) E_g(\text{eV}) = 1.24$  giving the correspondence between the band gap (electron volts) and the corresponding light wavelength and note that the optical absorption edge is not sharp but exhibits a long tail in the gap region.)

The chalcogenide glasses transmit light from the Urbach edge until the IR region where a second mechanism generates photon absorption. This phenomenon takes place in the low-energy region and arises from multiphonon processes associated with fundamental phonon vibrations of the material. In most of the chalcogen-derived glasses that contain heavy elements, the vibrational modes are at low energy and they exhibit excellent IR-transmitting properties. Most of the commercial chalcogen-based glasses such as AMTIR therefore have their IR cutoff after the  $12\mu\text{m}$  region and consequently cover the very strategic region  $8\text{--}12\mu\text{m}$ , corresponding to the second atmospheric window. This IR window is used for military and civil applications such as missile guidance, thermal imaging, and thermal detection, and so on. Chalcogen-based glasses can be shaped for making IR lenses and windows, and so on, as well as optical fibers used for carrying IR laser light from CO or  $\text{CO}_2$  lasers and for local thermal imaging of room temperature black-body emitters.

Recently, chalcogenide glass IR fibers have been used as optical sensors for recording, in situ, the IR signatures of all kind of molecules in chemistry and biology. The principle is based on the absorption of the evanescent light circulating on the surface of the fiber, by the materials entering into contact with the fiber especially in the part which has been tapered.<sup>24</sup>

Noncrystalline chalcogenides are semiconductors with an activation energy about half of the optical band gap. The glass  $\text{As}_2\text{S}_3$  taken as a prototype has the following characteristics:  $W_e = 1.14\text{ eV}$ ,  $E_g = 2.32\text{ eV}$ , and  $\sigma(300\text{ K}) \sim 10^{-17}\Omega^{-1}\text{ cm}^{-1}$ .

Irradiation of chalcogenide films with light having an energy comparable to the band gap induces a variety of

changes, such as photoluminescence and photoconductivity. Some of these are reversible and some are not, such as the chemical changes involved in lithography applications. Among the most peculiar photoinduced phenomena is the photodarkening corresponding to a reversible shift of the band-gap edge towards lower energy under illumination.

The electron–hole pairs created by illuminating the surface of a Se film is the basis of the xerography process. If the Se film is already positively charged, the photon from the ‘image’ of the page results in the excitation of an electron. This neutralizes a corresponding positive charge and leads to the formation of a positive electronic image. Carbon black particles are then deposited to give a black image of the documents.

As shown by Tanaka,<sup>25</sup> chalcogenide glasses are prone to photoinduced phenomena such as photorefractivity, photoexpansion, photofluidity, and so on which indicate that the local structure can be easily modified under suitable light irradiation.

## 4 HALIDE GLASSES

### 4.1 Introduction

Halide materials usually exist in the crystalline state when cooled from the liquidus. When the halogens are bound to small and highly charged cations, volatile molecular species such as  $\text{SiCl}_4$  are easily formed. Consequently, a very limited number of halide systems lead to glass formation and the glass to crystal or glass to molecular vapor competition is severe.

Considerable progress has been made during the last two decades in the discovery of new glass-forming compositions, based on group 7 elements (F, Cl, Br, I), characterized by the outer electronic shell  $s^2p_x^2p_y^2p_z^1$ , showing one bonding electron.

The optical properties, and especially the possibility of extending the IR transparency domain, have been the main motivation for investigating such exotic glasses. Three intrinsic factors limit the technological development of such vitreous materials. Like other halides, they suffer from ready corrosion by moisture or water driven by stronger  $\text{M-OH}_2$ ,  $\text{M-OH}$ , or  $\text{M-O}$  bonds. The relative weakness of the  $\text{M-X}$  bond also results in poor thermal capability, leading to low  $T_g$  glasses with high thermal expansion coefficients and sensitivity to thermal shock. Finally, the high electronegativity of the fluorine atom results in the easy formation of ionic bonding and leads to ionic microcrystal formation when crossing the strategic liquidus–solidus line. The optical properties, and especially the scattering losses, therefore suffer from the tendency to devitrify.

In addition to the development of very large IR optics, often difficult to accomplish with crystalline materials, an important property of halide glasses is the potential for the development of very transparent IR optical fibers. With its

unique viscosity–temperature dependence the glassy state represents an ideal situation for transforming a bulk material into a very long waveguide. Several articles reviewing the chemistry and optical properties of these materials have been published.<sup>26–28</sup>

## 4.2 Glass Formation in Halide Systems

Because of its size,  $r(\text{F}^-) \sim r(\text{O}^{2-}) \sim 1.40 \text{ \AA}$ , fluorine is a rather special halogen leading to materials which are generally less sensitive to water corrosion and which are more suitable for practical applications. Consequently, among all the halide compounds which have been claimed to form glasses, only a very limited number are stable enough to be considered as optical materials and this is the case for several fluoride glass compositions. The heavy halide glasses, that is, the chlorides, bromides, and iodides, are all characterized by a high hygroscopicity and, despite their scientific interest, have to be considered as technological curiosities.

### 4.2.1 Fluoride Glasses

Fluoride glasses can be classified according to structural considerations and although glass-forming ability has been observed in many fluorides they cannot be considered of equal interest because of the high tendency for most of them to devitrify.

In most of these systems, the tendency to ionicity is high, leading to strong glass to crystal competition. This article is restricted to the compositions that are stable enough to make bulk samples, having a significant optical quality either for fundamental investigations or practical applications.

In all the following systems, the polymerization process arises from the twofold coordination of the F atoms which connect the elementary polyhedra in a 3-D manner. The  $\text{F}^-$  ions situated between two highly charged  $\text{M}^{n+}$  cations appear to be strongly  $\text{sp}$  hybridized, with a strong delocalization of the electrons located in the  $\text{sp}_x$  orbitals towards the empty orbitals of the  $\text{M}^{n+}$  cation. The formation of long polymerized chains,  $\cdots \text{M} \leftarrow \text{F}^- \rightarrow \text{M} \leftarrow \text{F}^- \rightarrow \text{M} \leftarrow \text{F}^- \rightarrow \text{M} \cdots$ , contributes to the increase in the viscosity in the melt.

**$\text{MF}_2$ - and  $\text{MF}_3$ -based Glasses.** One of the oldest fluoride materials prepared in the glassy state is beryllium fluoride,  $\text{BeF}_2$ . This compound, isotypic with  $\text{SiO}_2$ , shows a strong resistance to crystallization and is based structurally on a giant aperiodic corner-sharing  $\text{BeF}_4$  tetrahedral framework. The main difference between the two glasses comes from the comparison between the bond strengths,  $\text{Be-F}$  and  $\text{Si-O}$ , which shows up in the difference in the glass transition temperatures,  $T_g(\text{SiO}_2) = 1100^\circ\text{C}$ ,  $T_g(\text{BeF}_2) = 250^\circ\text{C}$ . Despite the unique optical properties of  $\text{BeF}_2$ -based glasses owing to their very low refractive index ( $n = 1.27$ ) and low optical dispersion, these materials

suffer from high hygroscopicity and toxicity. Several mixed compositions containing  $\text{AlF}_3$  have been developed for high-power laser applications. This research has been pursued because of the interesting property that the low nonlinear refractive index reduces the risk of self-focusing and glass breaking.

The  $\text{MF}_3$ -based glass category is represented by  $\text{AlF}_3$  and the transition metal  $\text{MF}_3$  group with  $\text{M} = \text{Fe}, \text{Co}, \text{Ga}$ , and so on. By themselves the  $\text{MF}_3$  compounds do not give glasses; they need to be combined with glass modifiers and stabilizers<sup>29,30</sup> such as  $\text{PbF}_2$ . For instance, an interesting glass composition  $\text{PbFeMnF}_7$  is found in the ternary system  $\text{FeF}_3\text{--MnF}_2\text{--PbF}_2$  and this material, rich in magnetic ions, exhibits remarkable spin-glass properties at low temperature. It has also been recently demonstrated that a glass composition belonging to the  $\text{PbF}_2\text{--GaF}_3\text{--ZnF}_2$  system can be deposited as a thin layer on a cold substrate by physical vapor deposition.

The structural building units of these glasses are octahedral  $\text{MF}_6$  units which, by sharing corners, generate a skeleton related to the  $\text{ReO}_3$  structure. Most of these  $\text{MF}_3$ -based glasses show a great tendency to devitrify owing to the ionic character of the  $\text{M-F}$  bond.

**$\text{ZrF}_4$ -based Fluoride Glasses: ZBLAN glasses.** The fluorozirconate glasses, based on the glass-forming ability of  $\text{ZrF}_4$  when combined with other appropriate fluorides, have attracted considerable interest because of their promising optical properties in the mid-IR. Their discovery<sup>31,32</sup> resulted from a systematic investigation of ternary systems such as  $\text{ZrF}_4\text{--LaF}_3\text{--BaF}_2$  as shown in Figure 12.

**Figure 12** Glass-forming domain in the ternary diagram  $\text{ZrF}_4\text{--BaF}_2\text{--LaF}_3$ . The center of the vitreous area is represented by the ZBL glass. The composition  $\text{BaZr}_2\text{F}_{10}$  corresponds to a very unstable glass while ZBLA and ZBLAN (composition in molar % of fluoride) are the acronyms of two very stable glasses

The optimized composition corresponding to the glass having the lowest critical cooling rate  $R_c$ , in the range  $R_c \sim 1^\circ\text{C min}^{-1}$ , is the five-component glass ZBLAN:  $55\text{ZrF}_4\text{--}18\text{BaF}_2\text{--}6\text{LaF}_3\text{--}4\text{AlF}_3\text{--}17\text{NaF}$ . In this glass, the modifier cation  $\text{Ba}^{2+}$  has been partially replaced by  $\text{Na}^+$  and this introduces an interdiffusion barrier to devitrification because of the competition between Na and Ba fluorozirconate microcrystal formation. From this ZBLAN composition, large pieces of optical glasses of several kilograms, as well as low-loss optical fibers, have been prepared. The good behavior versus devitrification can be also understood by examining the differential scanning calorimetry (DSC) trace of a ZBLAN glass. The glass transition temperature at  $280^\circ\text{C}$  is far from the crystallization temperature ( $T_x \sim 400^\circ\text{C}$ ), marked by a small exothermic peak. The liquidus temperature is around  $550^\circ\text{C}$ .

The structural modeling of such glasses has been based on X-ray diffraction, molecular dynamics, and X-ray investigations of the parent crystalline materials<sup>33</sup> such as  $\text{BaZr}_2\text{F}_{10}$ . The 3-D skeleton as indicated in Figure 13 is built up from  $\text{ZrF}_7$  and  $\text{ZrF}_8$  polyhedra connected by corners or edges. The large  $\text{Ba}^{2+}$  cations are ionically bonded to the nonbridging fluorines and play the role of lattice modifiers.

Glass-forming ability has been also observed in several Zr-free fluoride systems, like in In-based glass systems whose

IR edge is shifted towards longer wavelengths, as compared to ZBLAN.

#### 4.2.2 Glasses Based on Heavy Halides

This terminology refers to glasses in which the electronegative part is a heavy halogen X ( $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ). Most of these materials suffer from strong moisture corrosion, low softening temperature, and a tendency to devitrify. The fundamental interest in such glasses is motivated by the fact that from a simple consideration of the masses of the anions, the heavy halide glasses would be expected to be more transparent in the IR than fluoride glasses.

### 4.3 Optical Properties of Halide Glasses

Considerable progress has been made during the last two decades in the discovery and investigation of halide glasses. The main justification of this research effort is the unusual and critical optical properties of these glasses. Unfortunately, the technical applications for most of them have been severely curtailed by their hygroscopicity and low thermal properties.

#### 4.3.1 Passive Optical Properties

The total intrinsic optical loss in an optical glass is due to three factors, and the corresponding attenuation coefficient  $\alpha$  can be expressed as:

$$\alpha = A \exp\left(\frac{-a}{\lambda}\right) + B\lambda^{-4} + C \exp\left(\frac{C}{\lambda}\right) \quad (1)$$

The first term is associated with multiphonon absorption mechanisms and is dependent on the IR edge. The second term represents the Rayleigh scattering and is due to electronic fluctuations on a microscopic scale. At long  $\lambda$ , this term is negligible. The third term, the Urbach tail, is related to the band-gap absorption and describes the limitation of transmission in the UV and visible part of the spectrum. In most of the halide glasses, the value of the band gap is high ( $E_g > 3\text{--}4\text{ eV}$ ), making these glasses transparent in the visible. This is in contrast to chalcogenide glasses that are always colored or black.

The most important feature of the halide glasses is associated with the possibility of controlling the phonon edge absorption mechanism by shifting the IR edge towards longer wavelengths. By combining all the intrinsic attenuation factors it can be seen in Figure 14 that a limited part of the optical spectrum corresponds to very low optical loss. This ultratransparency region is located close to  $1.55\text{ }\mu\text{m}$  for  $\text{SiO}_2$  glass with a minimum loss of  $0.16\text{ dB km}^{-1}$ , while the same minimum of the V-shaped curve is around  $3\text{ }\mu\text{m}$  for fluoride glasses with predicted ultralow-loss performance in the range of  $0.01\text{ dB km}^{-1}$ . To take advantage of this ultra

**Figure 13** Structural model for the binary glass  $\text{BaZr}_2\text{F}_{10}$ . The polyhedra  $\text{ZrF}_7$  and  $\text{ZrF}_8$  are connected by corners and edges to form the 3-D aperiodic framework where  $\text{Ba}^{2+}$  ions are statistically distributed

**Figure 14** Intrinsic optical loss versus wavelength for  $\text{SiO}_2$  and two fluoride glasses (Zr based and In–Ba based). The high transparency region for  $\text{SiO}_2$  glass is around  $1.5 \mu\text{m}$  with attenuation of  $0.2 \text{ dB km}^{-1}$ . The same ultrahigh transparency region is around  $3 \mu\text{m}$  for the fluoride glasses with the theoretical optical loss as low as  $0.01 \text{ dB km}^{-1}$

low-loss potential, optical losses of extrinsic nature should to be drastically reduced. The major two factors affecting the intrinsic glass transparency are:

1. colored impurities such as the transition metal ions of Fe, Cu, Co, Ni, and so on, or rare earths, characterized by parasitic absorption bands depending on  $\lambda$ ;
2. the scattering defects arising from glass imperfections such as microbubbles, microcrystals, inhomogeneities, metallic particles, microphase separation, and so on, related to the glass making technology.

To date, the best experimental results in terms of fluoride fiber attenuation is  $0.45 \pm 0.15 \text{ dB km}^{-1}$  at  $2.35 \mu\text{m}$ , measured for a 60-m-long ZBLAN fiber.

#### 4.3.2 Fluoride Glass Fiber Lasers

Fluoride glasses have a rather high capacity to accept doping elements such as rare earth ions, owing to their unusual structure. Several spectroscopic investigations conducted with doped glasses show unambiguously that the 4f ions substitute for  $\text{Zr}^{4+}$  in the glass-forming framework and are consequently subject to a rather well-defined ligand field corresponding to the usual coordination of  $\text{Zr}^{4+}$  which can vary from  $\text{ZrF}_6$  to

$\text{ZrF}_8$ . Analysis of spectroscopic data indicates that rare earth ions are eightfold coordinate as in the corresponding parent crystalline materials.

As a new optical host for active properties<sup>34</sup> fluoride glasses have the following characteristics.

1. The doping concentrations can be rather high.
2. The broadening of the emission or absorption spectra owing to the glassy state is very limited and the envelope of the peak is in the range of the Stark decomposition.
3. Excitation and emission can be observed in a large spectral domain,  $0.3\text{--}4 \mu\text{m}$ .
4. Compared to oxide glass matrices, such as silicates with a phonon energy at  $W_p = 1100 \text{ cm}^{-1}$ , the value of  $W_p \sim 500 \text{ cm}^{-1}$  in fluoride glasses corresponds to much lower nonradiative relaxation and consequently higher quantum efficiency for laser emission.
5. It is also observed that in these glasses up-conversion mechanisms are quite efficient, allowing the population of high energy levels with red or IR pumping.

One of the most spectacular results in the field of active optical properties have been obtained with fluoride glasses shaped into an optical fiber configuration. Indeed, rare earth-doped fluoride glass fibers have been shown to be excellent laser materials.<sup>35,36</sup> Core-doped fibers represent a unique optical geometry that offers high optical power confinement and thus efficient interaction between light and matter over long lengths. In addition, the fiber geometry is adequate for releasing the heat generated by possible nonradiative processes concomitant to lasing. More than 40 lasing wavelengths which range from the mid-IR at  $3.5 \mu\text{m}$  to the near-UV at  $0.45 \mu\text{m}$  have been observed. Blue or green lasers are obtained by up-conversion processes and diode pumping has been achieved, allowing the miniaturization of such a new source of light. Details on the lasing characteristics of rare earth-doped fluoride glass fibers can be found in Ref. 37.

#### 4.3.3 Fluoride Glass Optical Amplifiers

Optical amplifiers are essential components for the development of high capacity telecommunication networks. Silica fibers are characterized by a low-loss optical window that ranges from  $1.2$  to  $1.7 \mu\text{m}$ , as shown in Figure 4. That window is divided into the ultrashort (XS), short (S), conventional (C) and long (L) bands. The first two bands are centered at  $1.3$  and  $1.47 \mu\text{m}$ , while the C- and L-bands are equal to  $1530\text{--}1565 \text{ nm}$  and  $1565\text{--}1625 \text{ nm}$ , respectively. Amplification in the C- and L-bands is commonly achieved with  $\text{Er}^{3+}$ -doped silica fibers. On the other hand, amplification at  $1.47 \mu\text{m}$  and  $1.3 \mu\text{m}$  with  $\text{Tm}^{3+}$  and  $\text{Pr}^{3+}$  ions requires the use of materials with lower phonon energy than silica. High gain optical amplification was demonstrated in the XS, S, and C, telecommunication windows with rare earth-doped

fluoride glass fibers. With an estimated lifetime of more than 25 years in normal conditions, state-of-the-art fluoride fiber are compatible with long-term applications such as telecommunications, and *Real-world* amplifiers have been constructed and commercialized. Performances of nonoxide glass amplifiers can be found in Ref. 37.

#### 4.3.4 Fluoride Glass Channel Waveguides

Planar and channel waveguides can be obtained by ion-exchange technique with fluoride glasses. The experiment is carried out with  $\text{Er}^{3+}$ -doped ZBLA fluoride glass samples, treated by HCl gas at a temperature below the glass transition temperature  $T_g$  ( $T_g = 307^\circ\text{C}$  for ZBLA). The chemical reaction at the glass surface is:

where M represents all the cations in the glass.

Chloride ions, which substitute for part of the fluoride ions, modify locally the composition at the glass surface. The polarizability of  $\text{Cl}^-$  ions is greater than that of fluorides, and its introduction increases the refractive index. Then, ionic diffusion of  $\text{Cl}^-$  ions within the glass generates a gradient-index fluorochloride guiding structure.<sup>38</sup> Internal gain of  $3.9\text{ dB cm}^{-1}$  has been demonstrated at  $1.53\text{ }\mu\text{m}$  with such amplifying system.

## 5 METALLIC GLASSES

### 5.1 Introduction

As defined by Cahn,<sup>39</sup> a solid alloy with a liquid-like atomic arrangement is called a metallic glass, also called a metglass. Most of the metallic materials, which have been cooled to a state of rigidity without crystallization, are alloys and most of them have complex and well-defined compositions. As mentioned by Johnson in a well-documented article,<sup>40</sup> significant progresses have been made in the field, during the last decades and these noncrystalline solids, which were laboratory curiosities in the seventies, are now materials entering the market. This fast and spectacular evolution was due to the mastery of liquid alloy compositions exhibiting excellent resistance towards crystallization during the cooling process. For instance, in the sixties, the first liquid-metal alloys in the Au–Si system were vitrified in the Duwez group<sup>41</sup> by using ultrafast quenching techniques with very high rate of  $10^6\text{ K s}^{-1}$ , while for the last generation of multicomponent Zr–Ti–Cu–Ni–Be alloys, the critical cooling rate is only  $1\text{ K s}^{-1}$ , very similar to silicates or fluoride glasses. Consequently, the size of the glass samples has increased from a thickness of submillimeters to several centimeters.

As mentioned, the first glass-forming systems where fast quenching of the liquid was successfully applied were Au–Si and Pb–Si and it has also been observed that the most favorable region is close to a deep eutectic near 25 atom % Si. This observation is true for all the bulk glass-forming alloys and low-melting liquids are necessary to maintain a low thermal agitation which does not destroy the chemical bonds which take place in the melt and which is materialized by a significant increase of the melt viscosity. The nature of these chemical bonds is not yet well understood. However, clearly it ensures, in cooling, the formation of real out-of-equilibrium metallic glasses, exhibiting glass transition temperatures when reheated.

### 5.2 Glass-forming Alloy Systems

#### 5.2.1 Development of Bulk Metallic Glasses (BMG)

Turnbull<sup>42</sup> had predicted that the ratio of the glass transition temperature  $T_g$  to the melting point or liquidus temperature  $T_l$  of an alloy, was the essential factor. When the ratio  $T_g/T_l$  increases from value near 1/2 to values near 2/3, the homogeneous nucleation of crystallites in the undercooled melt is expected to become more sluggish. This assumption is verified by the work on Au/Si, Pd/Si, and Pd/Cu/Si and is still one of the best rules for predicting the alloys glass-forming ability. A ratio of 2/3 observed in the Pd/Ni/P system was in agreement with the easy glass formation of this alloy leading to bulk ingots of centimeter size for a cooling rate of about  $10\text{ K s}^{-1}$ .

Inoue and his group investigated the aluminum alloys combined with rare earth and transition metals such as the ternary alloys La/Al/Ni or La/Al/Cu. From there, they investigated more complicated alloys and demonstrated that the fabrication of glass samples having a thickness of about 1 cm was possible, for instance, in the alloys La/Al/Cu/Ni.

A similar family of excellent glass-forming materials was found in the alloys Zr/Cu/Ni/Al.

Zirconium-based alloys have received special attention, leading to the discovery, by Johnson group,<sup>40</sup> of several stable glasses and among them the complex composition  $(\text{Zr}_3\text{Ti})_{0.55}(\text{Cu}_5\text{Ni}_4)_{0.225}\text{Be}_{0.225}$ . This material called Vitreloy 1 (V1) is a commercial product used, for instance, for the fabrication of golf clubs.

Attention has been also paid to Fe/Co/Ni rich alloys owing to their magnetic properties. Bulk glass cylinders of 6 mm diameter has been prepared in the system Fe/Co/Ni/Zr/B.<sup>43</sup>

#### 5.2.2 Glass-forming Conditions

To make bulk glasses, one must frustrate the process of crystallization in introducing a kind of chemical disorder into the melt in order to avoid the dominant formation of one crystal species. This can be realized in mixing atoms having different

sizes and electronegativities, as well as dissimilar valence electrons configurations. In this situation, solid solutions exhibit critical maximum solubility and become topologically unstable. This destabilization is reflected in the phase diagram by a falling of the liquidus curve which results in a lower melting point which indicate that the liquid phase is stabilized relative to the crystalline phase.

These principles are well illustrated by one of the most stable metallic glasses, which has been discovered in the Zr/Ti/Ni/Cu/Be alloy and which contains four transition metals with very different chemistry and associated to Be, which is considered to be one of the most original elements because of its small size and valence electrons. Both Zr/Be and Ti/Be alloys show deep eutectic valleys in the transition metal-rich region. The same observation is made in the Zr/Ni and Cu/Ti binary alloys where the competing crystalline forms  $Zr_2Ni$  and  $Ti_2Cu$  limit the glass-forming ability.

It is not surprising that in the Zr/Ti/Ni/Cu/Be system, the five elements acts almost independently, each species preferring different nonequivalent crystallographic sites in the competing crystals. In this case, the alloys appear to be exceedingly frustrated leading in the best glass-forming region to liquidus temperature as low as 700 °C, with glasses having their  $T_g$  in the range 360–400 °C. This situation has permitted the fabrication of bulk glassy rods with thicknesses ranging between 5 and 10 cm.

### 5.2.3 Crystallization, Phase Separation

To better characterize the bulk glass-forming ability of metallic alloys, one needs to study crystallization kinetics in detail. An elegant method has been developed to examine nucleation and growth of crystals in the undercooled liquid. Container-less processing using high vacuum and electrostatic levitation provides a means of diminishing the influence of heterogeneous nucleation and facilitates the drawing up of the time-temperature-transformation (TTT) curve which give information on the nucleation and critical cooling rate.<sup>44</sup>

This method, when applied to the V1 alloy, indicates a critical cooling rate in the order of 1 to 2 K/s. For the same alloys the existence of liquid–liquid phase separation into beryllium-rich and poor liquids was also demonstrated. The knowledge of this complex phenomenon is important since it governs the nano-crystallization process and is, consequently, a good guide to select the suitable accurate glass composition. Phase separated domains have been also observed by transmission-electron-microscopy in the Mg/Y/Cu/Li alloys of the Inoue type, showing Cu-poor and Cu-rich regions.

It is also interesting to notice that the crystallization kinetics are also strongly affected by the presence of impurities, especially oxygen at a level below one percent molar. This contamination can alter the critical cooling rate by two order of magnitude. For instance, the glassy alloy V105, which has

the composition  $Zr_{52.5}Ti_5Cu_{17.9}Ni_{14.6}Al_{10}$ , is characterized by a critical cooling rate of  $1\text{ K s}^{-1}$  when pure. If contaminated by 1 at % of Oxygen, the glass formation requires rapid solidification, owing to a critical cooling rate which is increased to hundred of  $\text{K s}^{-1}$ .

It is also well known that one parameter preventing glass devitrification is associated to the presence of nonmetallic elements, such as Si, P, B, Be, and C, which play an essential role to slow down nucleation during cooling. It is very probable that these elements form clusters containing several metal atoms linked by a directed (partly) covalent bond. This phenomenon introduces a diffusion barrier to long-range organization, which decreases microcrystallite formation during cooling. The metallic radius mismatch between the constituent atoms improves the glass-forming ability by preventing the formation of extensive ordered solid solutions.

### 5.2.4 Viscosity of Metallic Glasses

The exceptional stability of the glass-forming compositions discovered during the last two decades has permitted far more extensive investigation of the temperature dependence of the viscosity for a deeply undercooled metallic system than possible previously. For example, in the 1970s, Chen<sup>45</sup> was limited in measurements to temperatures of only 20–30 K above  $T_g$ , by the lack of stability against crystallization of the Pd/Cu/Si alloy that he was studying.

As shown in the article by Johnson,<sup>40</sup> viscosity measurements on the Vitreloy glasses such as the V1, have been obtained, using various methods, in almost all the temperature domain, covering 15 orders of magnitude in viscosity.

The interesting news was in the comparison of these metallic glasses with the other glass-forming systems when introduced in the, now famous Angell<sup>46</sup> diagram, which represents the evolution of the viscosity of many glass-forming liquids versus temperature, more precisely  $T_g/T$ . From this universal diagram which allows the classification between strong and fragile glass-forming liquid, it is concluded that a glass such as the industrial alloy V1, exhibits a strong liquid behavior, similar to some silicate or fluoride glasses.

## 5.3 Properties and Applications of Metallic Glasses

### 5.3.1 Chemical Properties

Metallic glasses exhibit corrosion resistance that can be spectacular, owing to the absence of grain boundaries, with their frequent forms of chemical heterogeneity. The Fe-based glasses have been more extensively investigated and it has been observed that addition of Cr or Mo is particularly effective in increasing corrosion protection against acidic solutions. A glass such as  $Fe_{72}Cr_8P_{13}C_7$  passivates immediately in

concentrated HCl solution. Metallic glasses, especially when partially crystallized on a surface, can play the role of catalysts for gas-phase reactions such as the hydrogenation of CO or methanol synthesis. Owing to their excellent corrosion resistance, metallic glasses are good candidates for protective coatings against aggressive environments. Laser amorphization of the container surface as well as glass alloy sputtering have been used to produce corrosion resistant layers. This technology has been successfully applied for developing electrodes having a good electrocatalytic activity for  $\text{Cl}_2$  production while being resistant to oxidation by chlorine.

To avoid reaction between the Si substrate and Al metallizations during the manufacture of integrated circuits at high temperatures, diffusion barriers are necessary. It has been demonstrated that high crystallization-temperature glasses such as Ta–Ir glasses make excellent diffusion barriers in many microelectronics applications.

### 5.3.2 Magnetic Properties

For about two decades, amorphous iron based alloys are well known as good soft magnetic materials and alloys belonging in the Fe/Co/Ni/Zr/B system are among the best candidates owing to their interesting ferromagnetic properties. Their tendency to crystallize is such that their technological applications are limited, owing to the ribbon form in which they are commonly produced, in using fast quenching techniques such as the melt spinning or the twin-roller process represented in Figure 15.

As already mentioned, the optimization of the composition has allowed the fabrication of cylinders of a few millimeters diameters. Another alternative method has been recently developed in using successively ball milling of the thin alloy ribbons followed by a hot pressing operation in order to consolidate bulk samples.<sup>47</sup> Examination of the hysteresis loops reveal low coercive fields and fairly large saturation magnetization.

**Figure 15** Two selected methods for metallic glass preparation: (a) in the melt-spinning process the molten alloys are projected against a spinning wheel; (b) in the twin-roller quenching technique the melt is cooled between two rotating wheels. In both processes, the aim is to achieve ultrafast cooling

### 5.3.3 Mechanical Properties

The distinctive features of bulk metallic glasses (BMG) are their exceptional mechanical characteristics such as very high yield strengths and high elasticity limits. The elastic strain that a metallic glass can support in tension or bending is at least double that of ordinary commercially crystalline alloys and are therefore premier ‘spring’ materials because they can store high densities of elastic energy.

A variety of composite materials has been obtained by the direct introduction of a reinforcing crystalline solid phase into the glass-forming melt. In many cases, the resistance of the glass to crystallization is good enough to avoid any heterogeneous nucleation at the interface. As an example, the V1 alloy has been used as a glassy matrix to fabricate composite structures with diamond, SiC particles as well as tungsten metal powder or wires. In the case of the W/glass composites, it is proved that the glassy matrix induce localized shear deformation.

The capability to store elastic-energy density in a range of about four times the traditional alloy finds utility in the design of certain types of sporting equipment such as the golf club. This particular application exploits the high strength, favorable density, and ideal elastic behavior of a glass such as the vitreloy V1, which significantly allows to improve the performances of these new generation of iron-free golf clubs.

## 1 INTRODUCTION

Why would people be interested in metal–nucleic acid interactions? Perhaps because life as we know it is dependent on these interactions. Nucleic acids (DNA and RNA) are actually salts (or complexes) of metal ions from a chemical point of view. Therefore, it is difficult, if not impossible, to separate the behavior of DNA and RNA from their interactions with metal ions. We must also take into account specifically bound water molecules since they frequently mediate interactions between polynucleotides and metal ions.<sup>1,2</sup>

Metal ions are usually required to promote and stabilize functionally active or native conformations of nucleic acids, as well as to mediate nucleic acid–protein interactions. However, metal ions can also cause structural transformation of nucleic acids, or denature their native structures. In addition to structural roles, some metal compounds can induce cleavage (i.e. scission, fragmentation, or depolymerization) and modification (without cleavage) of nucleic acids. Metal–nucleic acid interactions can be either nonspecific or dependent on the chemical nature of nucleotide residues, nucleic acid sequence, or secondary and/or tertiary structure of nucleic acids. The specificity of these interactions is dependent

on structural and chemical properties of both the nucleic acids and the metal ions. There are two extreme views of such interactions. The first, among biochemists and molecular biologists, is that properties of metal ions are primitive in comparison with the properties of nucleic acids (presumably because of their smaller size); and the opposite one, common among inorganic chemists, who regard nucleic acids simply as big organic ligands. In reality, both nucleic acids and metal ions exhibit considerable complexity in their interactions, and such interactions could affect the chemical and biochemical properties of both participants.

The involvement of metal-containing species in nucleic acid-dependent processes, including nucleotide biochemistry; genetic information storage and transfer, and control of gene expression ( $\text{Mg}^{2+}$ );<sup>3–7</sup> mutagenesis (e.g.  $\text{Mn}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ , and  $\text{Ni}^{2+}$ );<sup>8–10</sup> chromosomal abnormalities (e.g.  $\text{Be}^{2+}$  and  $\text{Hg}^{2+}$ );<sup>11,12</sup> and carcinogenesis (e.g.  $\text{Ni}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Fe}^{3+}$ , and  $\text{Be}^{2+}$ )<sup>8,13–16</sup> is well documented (*see Metal Ion Toxicity and Metal-related Diseases of Genetic Origin*). There are only a few processes for which it is clear that the nucleic acid is the primary target of metal action.<sup>11</sup> In most cases, it is not clear whether the observed effects actually result from direct metal ion–nucleic acid interaction, since other species, such as specific proteins (*see Zinc: DNA-binding Proteins*), may be mediators between the metal ion and the nucleic acid in these processes *in vivo*.<sup>7,11,17,18</sup> To better understand mechanisms of metal–nucleic acid interactions occurring *in vivo*, numerous *in vitro* studies of model reactions and structures of metal–nucleic acid complexes have been carried out (*see reviews*<sup>19–37</sup>). The interactions of nucleic acids with so-called ‘biological’ metal ions, that is,  $\text{K}^+$ ,  $\text{Na}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Mn}^{2+}$ ,  $\text{Fe}^{2+/3+}$ ,  $\text{Co}^{2+/3+}$ ,  $\text{Cu}^{+/2+}$ , and  $\text{Zn}^{2+}$ , result in unstable, short-lived complexes with nucleic acids in which ligands bound to metal ions can undergo fast exchange.<sup>37–41</sup> That sometimes creates problems in structure determination of such labile complexes. In contrast, some nonbiological metal ions, for example,  $\text{Pt}^{2+/4+}$ ,  $\text{Pd}^{2+}$ ,  $\text{Ru}^{2+/3+}$ ,  $\text{Au}^{3+}$ ,  $\text{Hg}^{2+}$ , and  $\text{Ag}^+$ , form inert complexes with nucleic acids, which are convenient for isolation and investigation; numerous structural studies of such complexes have been described.<sup>26,42,43</sup> Such studies have also led to an interesting body of chemical knowledge, independent of the biological relevance of the species involved.

Eight general research areas can be argued to have contributed the most to what is known today about metal–nucleic acid interactions. The first involves studies of the mechanisms of antitumor activity of certain platinum compounds (*see Platinum-based Anticancer Drugs*), which are believed to have nucleic acids as a critical target.<sup>43–47</sup> The second is concerned with studies of the binding of biological and nonbiological metal ions with nucleobases, nucleosides, and nucleotides.<sup>25,30,35,42,48–50</sup> The third involves studies of metal-binding centers in tRNA molecules,<sup>51–54</sup> catalytic RNAs (ribozymes),<sup>53,55–58</sup> and synthetic oligonucleotides that constitute fragments of natural nucleic acids.<sup>53,59–66</sup>

The fourth area involves studies of the role of metal ions (including  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Mn}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Zn}^{2+}$ , and  $\text{Pb}^{2+}$ ) in mechanisms of chemical reactions catalyzed by ribozymes, which could play a key role in the origin of life (RNA World hypothesis).<sup>39–41,57,67–69</sup> The fifth involves the same metal ions (as well as  $\text{Ni}^{2+}$  and  $\text{Cu}^{2+}$ ) as catalysts in reactions that could have resulted in prebiotic synthesis of nucleotides and oligonucleotides.<sup>70–74</sup> The sixth involves the use of certain metal ions and complexes as heavy-atom labels (e.g. for electron microscopy and X-ray crystallography), as well as chemical and spectroscopic probes of nucleic acid structure and function.<sup>75–86</sup> The seventh involves the use of metal compounds as biological diagnostic tools in nucleic acid-based assays and biosensors.<sup>46,87–92</sup> Finally, the eighth area is concerned with the development of applications of metal-nucleic acid complexes in nanotechnology (i.e. microarrays and biochips).<sup>87,91–95</sup>

## 2 PROPERTIES OF NUCLEIC ACIDS ESSENTIAL FOR BINDING WITH METAL IONS

### 2.1 Chemical Structures of Nucleic Acids

The chemical structure of nucleic acids<sup>96</sup> provides wide varieties of metal-binding centers that can be involved in the formation of ionic, coordinative (donor–acceptor), hydrogen (H-), and covalent bonds. The term ‘nucleic acid’ is usually used to refer to polynucleotides. The monomeric unit (a nucleotide) consists of a single heterocyclic nucleobase, which can be a purine (adenine or guanine) or pyrimidine (cytosine, uracil, or thymine), attached through an N-glycosyl bond to a pentose sugar (a nucleoside), which in turn is attached to a phosphate by a phosphodiester bond at the 5'- or 3'-terminus (Figure 1). Nucleotides (NMP, where is N = adenosine, A; guanosine, G; inosine, I; cytidine, C; thymidine, T; or uridine, U) can be linked together through 5' → 3' phosphodiester bonds to produce linear oligonucleotides (usually <100 nt in length) and polynucleotides (>100 nt), or conjugated to additional phosphate groups to form nucleoside di- and triphosphates (NDPs and NTPs, respectively). Phosphate groups can be attached to a nucleoside through 5'- and 3'-hydroxyl groups of the pentose rings. There are two classes of nucleic acids; those in which the sugar residue bears a hydroxyl group at the 2'-position (ribonucleic acid, RNA) and those in which it does not (deoxyribonucleic acid, DNA). In DNA, the commonly occurring heterocyclic bases are adenine, guanine, cytosine, and thymine, whereas in RNA, thymine is replaced by uracil. The heterocyclic bases are essentially planar, with exocyclic groups lying in the plane of the rings and lone-pair electrons delocalized into the  $\pi$ -systems of the rings. The tautomeric forms of the bases (imino forms for guanine, adenine, and cytosine or enol forms for guanine, cytosine, uracil, and thymine), which are alternatives to the structures

**Figure 1** Structures of the nucleic acids and their constituents

presented in Figure 1, do not ordinarily exist in significant concentrations in solution.<sup>97</sup> In comparison to DNA, RNA molecules also have a 2'-OH group that may provide more structural complexity at polynucleotide level and more options for metal binding, as well as higher chemical stability under acid pH conditions. However, the 2'-OH group also makes RNA subject to depolymerization through transesterification catalyzed by many polyvalent metal ions ( $M^{\geq 2+}$ ) at neutral and alkali pH, while such reactions do not normally occur with DNA (see Section 7).

Nucleic acid residues are highly hydrated in water solutions and crystals: two  $H_2O$  per phosphate diester and up to six per base pair in DNA and RNA.<sup>2,98,99</sup> There are at least two different types of water molecules bound to nucleic acids. The first involves a highly ordered hydration shell, which is a layer of water molecules interacting via H-bonds primarily with hydrogen bond donor and acceptor groups of nucleic acid residues. These water molecules play important roles in both intra- and intermolecular interactions between nucleic acid residues as well as in metal–nucleic acid interactions that require the interacting surfaces (of both nucleic acids and metal ions) to be partially dehydrated so that either direct (inner-sphere) bonds or bonds through water molecule (outer-sphere) can form.<sup>1,57,99–104</sup> The second water layer is only partially ordered and weakly bound to nucleic acids (through secondary H-bonds or induced dipole–dipole interactions) making it easily exchangeable with bulk water molecules and metal ions. The polarization capability of water molecules can weaken electrostatic interactions between nucleic acids and metal ions.<sup>104</sup>

## 2.2 Potential Metal-binding Sites in Nucleotides and Nucleosides

Many donor and acceptor atoms in nucleic acids are capable of participating in indirect (outer-sphere) binding through H-bonds with water molecules or other ligands coordinated to metal ions. To understand the direct (inner-sphere) binding between nucleic acid residues and metal ions, both the nucleophilicity and basicity<sup>28</sup> of potential metal-binding sites must be considered. At neutral pH, the principal metal-binding sites in nucleotides (with  $pK_a$ 's at ionic strength  $I = 0.1$  in parentheses) include: terminal phosphate oxygens (1.0 and 6.6), internucleotide phosphate oxygens (1.0), and endocyclic atoms in guanosine (N-7, 2.0), adenosine (N-7 or N-1, 3.8), and cytidine (N-3, 4.2).<sup>28,42</sup> The purine N-3 nitrogen is generally sterically hindered by the sugar and does not bind metal ions, but changing the relative orientation of the nucleic acid base and sugar can make this site available for metal-ion binding. The exocyclic  $O^2$  atom of cytidine is well established as a metal donor atom and constitutes the most important exocyclic metal-ion binding site at neutral pH. The carbonyl groups of other nucleic acid bases, in comparison, are relatively weak donors and usually only bind metal ions if other functional groups participate as well.

Upon deprotonation, some endocyclic nitrogen atoms, notably guanosine N-1 ( $pK_a = 9.3$ ), uridine N-3 (9.5), and thymidine N-3 (9.9) become binding sites as well. The exocyclic  $NH_2$  groups in adenosine and cytidine, as well as the ribose 2'-OH group, are poor ligands even when deprotonated ( $pK_a > 12$ ). However, for some metals, binding at specific secondary binding sites can be favorable enough that binding takes place at a pH considerably lower than the nominal  $pK_a$ .

There are also metal interactions that do not involve coordination chemistry. For example, cytidine and uridine can form covalent bonds with Hg via C-5.<sup>105,106</sup> Another metal-binding site is the 5,6-alkenic bond in thymidine, which can be oxidized by hexavalent Os or by heptavalent Mn.<sup>105</sup>

All transfer RNAs (tRNAs) contain a number of modified nucleobases and typically 2'-*O*-methylated nucleosides.<sup>107,108</sup> DNA also contains a more limited number of such species. Some of these modifications, for example, N-7 methylation of guanosine, diminish the metal-binding ability of the bases. A few functional groups, such as the exocyclic S in 4-thiouridine and 2-thiocytidine and the exocyclic substituent in 5-carboxymethylaminomethyluridine, enhance the ambivalent nature of the bases.<sup>35</sup> Some of these modifications change the basicity of primary metal-binding sites.

To create new metal-binding centers or affect the stability and specificity of existing metal–nucleic acid bonds, certain nonnatural derivatives of nucleic acid bases, sugars, and phosphates have been artificially designed. One example is the thiophosphate moiety, in which one nonbridging or bridging oxygen of the normal phosphate diester is substituted by a sulfur atom (see Figure 1).<sup>109,110</sup> To remove or shield specific metal-binding sites, selected nucleic acid residues can also be modified (e.g. by ethylation of phosphate ester oxygens or methylation of ring nitrogen atoms in purine nucleotides).<sup>111,112</sup>

## 3 POSSIBLE EFFECTS OF POLYNUCLEOTIDE STRUCTURES ON METAL-ION BINDING

### 3.1 Polyelectrolyte Effect

The initial interaction between positively charged metal ions and the negatively charged phosphate groups of nucleotides and polynucleotides involves a fast electrostatic interaction that is weak and nonspecific.<sup>37,103,104,113</sup> For example, the increasing phosphate content (and hence negative charge) in the series  $A < AMP < ADP < ATP$  governs the increase in affinity toward alkaline earth metal ions, which bind predominantly to the phosphate groups of nucleotides.<sup>114,115</sup> The cation concentration in proximity to the polynucleotide polyanions is far higher than in the bulk solvent.<sup>116</sup> For low ionic strength solutions of DNA, the ratios of these concentrations ('the polyelectrolyte effect') for  $Na^+$  and

$\text{Mg}^{2+}$  were estimated to be roughly  $3 \times 10^3$  and  $9 \times 10^6$ , respectively,<sup>22</sup> reflecting the greater attraction of divalent cations.<sup>116</sup> However, at a high ratio of monovalent to divalent cations, a competition for the available phosphate anion binding sites occurs, in addition to the dielectric effects of single charged cations; in some cases, this can effectively shield the negatively charged sites from polyvalent cations.<sup>10</sup> The electric field produced by a polyanion in association with that of the compensating counterions increases the  $\text{p}K_{\text{a}}$  values of the nucleic acid bases slightly and promotes polarization of water molecules bound both to the nucleic acid and metal ions.<sup>98</sup>

The negative charge density, and hence the polyelectrolyte effect, is smaller for single-stranded polynucleotides than for multistrand species (see below).<sup>22</sup> Nonspecific binding of metal ions with nucleic acid phosphates exhibits negative cooperativity, because bound cations reduce the net charge of the polyanion.

Nucleic acids usually bind alkali monovalent metal ions only in an ‘atmospheric manner’ (in which the  $\text{M}^+$ –phosphate distance is larger than 7 Å).<sup>37,117</sup> For polyvalent metal ions, two additional types of binding have been characterized: outer-sphere binding, in which a water molecule coordinated to the metal ion produces a hydrogen bond with the phosphate

oxygen, and inner-sphere binding, in which the metal ion is bound directly to the phosphate oxygen (the  $\text{M}^+$ –phosphate distances associated with these two mechanisms are about 6 and 3 Å, respectively).<sup>117</sup> Because the ionic radii of divalent metal ions (Table 1) are about 10-fold smaller than the distance between adjacent phosphates in stacked polynucleotide chains, divalent metal ions generally do not bind with two phosphates simultaneously by an inner-sphere mechanism.<sup>118</sup> As was demonstrated for the interaction between  $\text{Mg}^{2+}$  and oligoriboadenylates, short flexible oligonucleotides may more easily bend to afford a loop structure in which two phosphate residues can provide full charge compensation by binding directly to a single metal ion.<sup>118</sup>

For many metal ions, the initial electrostatic interaction can be followed by stronger and more specific binding with nucleic acids via the formation of outer- and inner-sphere complexes. The formation of such complexes may be strongly accelerated (in comparison to binding to nucleosides and nucleotides) because of the polyelectrolyte effect.

### 3.2 Internucleotide Interactions

In addition to the polyelectrolyte effect, nucleotide sequence (or primary structure), and secondary and tertiary

**Table 1** Basic features of hydrated metal ions involved in metal–nucleic acid interactions

| Ion                | Ionic radius <sup>119,120</sup> | Coordination number <sup>120</sup> | Typical geometry of inner-sphere complex <sup>120</sup> | First $\text{p}K_{\text{a}}$ of $[\text{M}(\text{H}_2\text{O})_n]^{M+a}$ , <sup>121,122</sup> |
|--------------------|---------------------------------|------------------------------------|---------------------------------------------------------|-----------------------------------------------------------------------------------------------|
| $\text{Ag}^+$      | 1.26                            | $2 > 4$                            | Linear                                                  | 9.8–11.7                                                                                      |

<sup>a</sup>Dependent on ionic strength.

structures of single-stranded polynucleotides may dramatically affect the kinetics, mode, and affinity of metals ion binding through internucleotide interactions (base stacking, H-bonds) and the spatial arrangement of potential metal-binding centers (steric effects). These characteristics also vary among different types of polynucleotides. For example, the affinity of  $\text{Mg}^{2+}$  for individual types of polynucleotides is in the order  $\text{tRNA} > \text{poly(I)} \gg \text{poly(A)} \sim \text{poly(A)}\cdot\text{poly(U)} \sim \text{poly(I)}\cdot\text{poly(C)} \sim \text{DNA} \geq \text{denatured DNA} > \text{poly(C)} > \text{poly(U)}$ .<sup>123</sup>

### 3.2.1 Base Stacking

In solutions of ordered polynucleotides, the heterocyclic bases are stacked, that is, packed vertically one upon the next. The greatest stability is for purine–purine base-stacking interactions. The next are purine–pyrimidine interactions, which in turn impart greater stability than pyrimidine–pyrimidine stacking interactions.<sup>124,125</sup>

Base-stacking interactions may strain or disrupt metal binding. This can occur in the plane of the nucleobase heterocycles, owing to the absence of proper geometry for chelation of neighboring nucleobases (e.g. binding of *cis*-( $\text{NH}_3$ )<sub>2</sub>PtCl<sub>2</sub> with neighbor purine bases),<sup>47</sup> and also for binding from above or below the plane (e.g. for the 5,6-double bond of T), because of steric hindrance.<sup>96,125</sup> Alternatively, base stacking can actually favor metal  $\pi$ -complex formation where the metal ion is inserted between two stacked bases.<sup>125</sup>

### 3.2.2 Hydrogen Bonds

The main factor determining the specificity of intra- and intermolecular interactions of polynucleotide chains is interbase H-bonding interactions, which occur between the amidate or exocyclic amine nitrogen donors of one nucleobase and the keto oxygen or heterocyclic nitrogen acceptors of another base.<sup>97,125</sup> The common H-bonding schemes involve Watson–Crick base pairs: A·T (A·U) and G·C or I·C in DNA (RNA) duplexes; T·A·T (or U·A·U) and C<sup>+</sup>·G·C in triplexes; and G<sub>4</sub> in quadruplexes (Figure 2). There is also evidence for a few other types of interbase arrangements, for example, Hoogsteen and reverse Hoogsteen base pairs.<sup>126</sup> In some cases, nonWatson–Crick interactions may occur as frequently as Watson–Crick base pairs and play an important role in stabilizing the structure of RNA, for example, for G·U base pairs and tertiary (nonduplex) A·G pairs in tRNAs (Figure 2b)<sup>124</sup> and the active center of the hairpin ribozyme.<sup>127</sup>

As a consequence of base pairing, only a limited number of possible metal-binding sites in the bases are available in duplexes;<sup>37,130</sup> even fewer sites are accessible in triplex and quadruplex structures (Figure 2). The electron density of donor atoms that remain available for metal binding also differs from the electron density in isolated base residues.<sup>32</sup> For example, the affinity of purine N-7 and N-3 atoms for

**Figure 2** Structures illustrating cross-sections of nucleic acid duplexes, triplexes, and quadruplexes<sup>76,128,129</sup>

metal ions is greater in DNA duplexes than for the free nucleotides.<sup>125</sup>

There are a few additional types of H-bonds in nucleic acids. For example, the sugar 2'-OH group in RNA can act as a H-bond donor to the neighboring 3'-phosphate oxygen

anion.<sup>97,125</sup> The hydrogen atoms of water molecules interact with phosphate oxygen anions and sugar OH groups; water oxygen atoms form bonds with donor (N–H and C–NH<sub>2</sub>) atoms in the nucleobases, while water hydrogen atoms interact with acceptor (N and C=O) atoms/groups. The hydrogen atoms of pentose 2'-OH groups in RNA also can interact with water oxygens. Such complex arrangement of internucleotide interactions between bases, sugar, and phosphate residues occurring in a GAAA tetranucleotide loop of a hairpin RNA is illustrated in Figure 3.

Interactions of the same water molecules with RNA nucleotides (via H-bonding) and metal ions (via inner-sphere coordination) could stabilize specific metal ion–nucleic acid complexes (e.g. in Mg<sup>2+</sup>–tRNA chelates)<sup>52</sup> and also create the possibility for direct proton transfer through a 'water chain' that could play a role in ribozyme–metal ion catalysis<sup>133</sup> and in the mechanism of metal-dependent nucleases and polymerases.<sup>134</sup> Similar types of H-bonds between different nucleotide residues have been found in tRNA tertiary structures, where they provide additional stabilization of tertiary interactions.

**Figure 3** Structural features for the GAAA tetranucleotide loop in the hairpins. (a) General scheme of specific contacts between bases (boxes), sugars (large circles) and phosphates (boldface small circles). Hydrogen bonds and stacking interaction are shown by dotted lines and by a black box, respectively. (b), Putative hydrogen bonding network with the guanosine residue in the GAAA tetraloop structure. The N7 atom of the A<sup>2</sup> residue can make a hydrogen bond with 2'-hydroxyl group of G<sup>131,132</sup>

### 3.3 Intra- and Intermolecular Structures Formed by Polynucleotides

#### 3.3.1 Secondary Structures

Single-stranded regions exist in most of the naturally occurring single-stranded RNAs, and in a few viral DNAs, as well as in denatured (see below) double-stranded DNAs. The single polynucleotide chains in solution may assume flexible right-handed helical structures as a result of base stacking and intramolecular H-bonds.<sup>124</sup> However, there are mostly short single-stranded regions present in single-stranded polynucleotides. As a result of folding back of the single polynucleotide strands, complementary H-bonds may form between bases, producing intramolecular duplexes and triplexes (see below) as well as internal loops, hairpin loops, and bulges (Figure 4a). Such structures, whether formed intra- or intermolecularly, are secondary structure elements.

The most prominent motif, which binds together all other secondary structure elements, is duplex (double helix). Most natural DNAs and a few viral RNAs are double-stranded and normally present in solution as duplexes, which are antiparallel (in terms of strand orientation), right-handed double helices (Figure 5, A–B), stabilized through base–base interactions by both stacking and Watson–Crick H-bonding (see Figure 2). Double-stranded structures are less flexible than single-stranded ones, which limits the number of nucleic acid ligands that may participate in chelation of metal ions. In addition to the specific interbase (stacking and complementary) interactions, the restricted conformational freedom of pentose rings (involving C-2' and C-3'-endo conformational isomers) and rotation about single bonds (see Figure 1), as well as steric (i.e. nonbonding) interactions between the bases and sugars, and electrostatic repulsion between phosphate groups, result in a limited variation in double helical structures. The conformational flexibility of double-stranded RNA is even more limited because of the added bulkiness of the 2'-OH group in ribose residues, which stiffens the sugar–phosphate backbone. In normal B-form DNA (Figure 5, B) the base pairs, intersecting at the helix axis and stacking perpendicular to it, form a central hydrophobic pillar surrounded by the hydrophilic sugar–phosphate backbone. In the usual A-form RNA double helix, the base pairs are located away from the center and tilted about 15° from the helical axis (Figure 5, A). There are other significant differences between these forms, such as the diameter of the backbone cylinder (which is slightly narrower in B-form than in A-form duplexes), the number of base pairs per helix turn (approximately 10 vs. 11), and the axial rise per base pair (3.4 vs. 2.8 Å for DNA and RNA duplexes, respectively). These structural features produce a major groove that is deep and narrow in A-form duplexes and a shallow, wider minor groove. In contrast, B-form duplexes have a wide major groove and narrow minor groove; both are of comparable depth (Figure 5). In the major groove of B-form DNA, potential metal-binding centers – atoms N-7 and

**Figure 4** Tertiary structures of RNA's including (a) various stems, loops, and bulges, (b) an RNA pseudoknot. (Reprinted from Ref. 135, © 1990, with permission from Elsevier)

O<sup>6</sup>(N<sup>6</sup>) of the purines and O<sup>4</sup>(N<sup>4</sup>) of the pyrimidines are quite accessible; this is also true for N-3 of purines in the minor groove of DNA.<sup>136,137</sup>

Under conditions of reduced hydration, for example, in the presence of either high salt (of certain monovalent cations) or ethanol concentrations, or in crystals, DNA may adopt the A-form.<sup>99</sup> DNA–RNA hybrids (an intermediate in both forward and reverse transcription) exist as A-form duplexes.<sup>126</sup> Alteration of a duplex conformation can dramatically affect the accessibility of potential metal-binding sites.<sup>37,139</sup>

The most striking structure that has been observed for a DNA duplex is the left-handed Z-form DNA having Watson–Crick base pairing and a 'zigzag' sugar phosphate

backbone (Figure 5, Z); this structure forms in alternating pyrimidine–purine sequences (e.g. CGCGCG) in the presence of appropriate polyvalent metal ions. The transition from B- to Z-form DNA is facilitated enormously by certain divalent metal ions, reflecting the importance of this metal ion to the stabilization of Z-DNA structure.<sup>140,141</sup> Z-form DNA is believed to exist in specific regions of DNA *in vivo*, and may play an important role in functions such as regulation of gene expression.<sup>124</sup>

Covalently closed circular DNAs exist in nature in a variety of organisms. Such topologically constrained DNAs can form both negatively supercoiled structures, which create a torsional stress on the double helix and favor its unwinding, and positively supercoiled molecules, which enforce tighter winding of the double helix. When the sugar–phosphate backbone of even one strand is broken, the supercoils are relaxed, forming an open circle of duplex DNA. Such backbone cleavage reactions can result from the action of metal compounds on DNA.<sup>12</sup>

DNA is prone to structural polymorphism: its structure can differ markedly from the classical double helix. For example, under superhelical stress, circular closed DNA can adopt an unusual structure, denoted H-DNA, in which homopurine–homopyrimidine tracts unwind and utilize the pyrimidine-rich strand to form an intramolecular triplex with another homopurine–homopyrimidine tract; the remaining purine single strand is left unpaired. The formation of H-DNA requires the presence of metal ions such as Mg<sup>2+</sup> or Ca<sup>2+</sup>.<sup>142,143</sup>

The great interest in triple-helix formation relates less to its possible physiological significance (which is currently unclear) than to potential applications (e.g. in gene-targeted therapy and genetic engineering) that can exploit the ability of single-stranded oligonucleotides to bind selected double-stranded DNA sites.<sup>144</sup> In triplexes composed of one polypurine and two polypyrimidine strands, the polypyrimidine 'third' strand lies in the major groove parallel to the purine strand of an A-form double helix. This additional strand interacts with the Watson–Crick duplex via Hoogsteen base pairing to form T·A·T and C<sup>+</sup>·G·C triplets (see Figure 2c). The formation of the latter triplet is optimal at acid pH and markedly decreased at pH > 6 because of the need for cytidine protonation. However, the use of certain base analogs and phosphodiester backbone modifications allows triplex formation at physiological pH.<sup>144</sup> There are a few others type of triplexes that have been observed including G-rich pyrimidine–purine–purine structures.<sup>144</sup> Not surprisingly, triplex formation affects accessibility of potential metal-binding sites and requires certain divalent metal ions to stabilize the repulsion resulting from the negatively charged backbones of polynucleotide strands brought into close proximity. However, metal ions may both stabilize and destabilize the formation of triplex structures (see Section 6).

Both natural and synthetic polynucleotides containing repeats of G-rich sequences can also form quadruplexes (see

**Figure 5** Structures of A, B, and Z-form DNAs<sup>138</sup>

Figure 2d), including parallel interstrand (most stable) and antiparallel intrastrand (fold-back) structures in DNA and RNA. These types of multistranded DNA structures have been proposed to be important in chromosomal telomere formation, immunoglobulin gene switching, and genetic recombination.<sup>129</sup> The large hydrophilic channel within the quadruplex structure is stabilized by monovalent metal ions such as  $K^+ > Rb^+ \sim Na^+ > Li^+$  (in order of their effectiveness)<sup>129,145–147</sup> (also see Section 6).

### 3.3.2 Tertiary Structures

The structures described above, whether formed intra- or intermolecularly, are secondary structure elements. Additional

interactions between these secondary structure elements, for example, base pairing between two loops or between a loop and a single-strand region, constitute tertiary structure (Figures 4b and 6). Most known tertiary interactions (including base triples, intercalation (insertion) of a base from one secondary structure element between two neighboring bases in another, and pseudoknots) have been found in RNA molecules, including tRNA.<sup>124,148</sup> DNA supercoiling (see above) is a feature of tertiary structure as well.

Single-stranded regions of nucleic acids provide metal ions with access to all possible binding sites in the nucleotide residues. In contrast, nucleic acid tertiary structure, while creating some restrictions on metal binding in certain regions, may also provide other sites at which donor atoms located

Likewise, duplex stability tends to increase as the number of base pairs increases. Because there is electrostatic repulsion between negatively charged oxygens in the sugar–phosphate backbone, the structures of multistrand polynucleotides are unstable in pure water at temperatures above 0 °C; their stabilities increase with increasing concentrations of monovalent metal cations that act as counterions for the phosphate oxygens.<sup>154</sup> The influence of di- and trivalent metal ions on the stability of nucleic acids is more complicated and may be both stabilizing and destabilizing (see below).<sup>7</sup> Usually, the relative stability of nucleic acid hybrids increases in the order DNA–DNA < DNA–RNA < RNA–RNA.<sup>155</sup> In addition to elevated temperature, extremes of pH also may be used to disrupt multihelical polynucleotide structures, since protonation or deprotonation of bases involved in H-bonding destabilizes base pairing. Alkaline conditions (pH > 11.5) are suitable for denaturation of DNAs, but not for RNAs, which are cleaved at high pH. In comparison, acidic conditions (pH < 2.5) are suitable for denaturation of RNA, but cause depurination of DNA.<sup>154</sup> Some proteins can also induce local denaturation of DNA.<sup>156</sup> When the temperature or pH is restored smoothly to the ‘biological’ range (25–45 °C and pH 7–8, respectively), the denatured strands can renature to restore the intact duplex, but fast cooling (e.g. in ice) or shifting to neutral pH typically results in intrastrand collapse without proper interstrand base pairing. Denaturation of multistrand polynucleotide structures usually increases accessibility of potential metal-binding sites but may decrease or change the specificity of metal binding (see below).

The difference between native and denatured forms of RNA tertiary structures<sup>124,157</sup> are not quite as simple (or clear) as in the case of multistrand DNA structures. Stabilization of the RNA tertiary structures by metal ions and changes in metal-binding modes upon denaturation are based on a similar principle as for DNA but apparently are more complex processes.<sup>57,104,157–163</sup> For example, specific tertiary structures of tRNA molecules can exist at high concentration of Na<sup>+</sup>, but are very unstable in the absence of divalent metal ions.<sup>159</sup> The tRNA tertiary structure provides the specific binding sites for divalent metal ions (naturally – Mg<sup>2+</sup>) (Figure 6), which disappear with the liberation of the bound metal ions as a result of the tertiary structure unfolding under denaturing conditions.<sup>158</sup> However, if all endogenous Mg<sup>2+</sup> ions were removed from a tRNA molecule (e.g. by heating the solution in the presence of excess of strong chelating agents such as EDTA) and then added back to solution in exactly the original amount, the native tertiary structure can be restored, but not for each tRNA molecule,<sup>160</sup> presumably because Mg<sup>2+</sup> ions can stabilize both native RNA structures and also can trap RNA in relatively stable ‘alternative’ structures.<sup>164</sup> Interestingly, some RNA complexes containing certain metal ions (e.g. Mg<sup>2+</sup> and Mn<sup>2+</sup>) can survive under ambient temperatures even in the presence of EDTA (despite the strong metal affinity of EDTA: log K stability for [Mg<sup>2+</sup>–EDTA] and [Mn<sup>2+</sup>–EDTA] are 9.1 and 14.0, respectively<sup>121</sup>) presumably

because of the electrostatic repulsion and steric inaccessibility of EDTA to some metal ions bound in internal pockets of RNA tertiary structure.<sup>158,161,165</sup> For this reason, to most effectively remove divalent (or trivalent) ions bound to RNA, the RNA should be heat-denatured in the presence of chelating agents and high concentrations of monovalent cations to accelerate ligand-exchange reactions if possible.<sup>161</sup>

### 3.4 Structure-Specific Binding of Metal Compounds to Polynucleotides

The specificity of metal ion/compound binding to a polynucleotide depends on its nucleotide sequence and structure as well as presence of modified nucleotides and reaction conditions (e.g. metal concentration, pH, and temperature). The specific binding always involves the formation of comparatively thermodynamically stable or kinetically inert (see below) metal–nucleic acid bonds. The term ‘comparatively’ means that the relative (not absolute) stability or inertness of the different bonds constitute the principal determinant of the specificity of interaction. There are different kinds of metal-binding selectivity, including (1) ‘atom-specific’ interactions, involving individual donor atoms in the nucleic acid residues; (2) ‘group-specific’ interactions, involving combinations of nucleotide residues such as phosphate, sugar, and nucleic acid bases; (3) ‘base-specific’ interactions in polynucleotides; (4) ‘sequence-specific’ interactions; (5) interactions specific to secondary structure, that is, involving binding to single-stranded or double-stranded polynucleotides; and (6) ‘tertiary structure-specific’ interactions, which are usual for RNA molecules and nucleoprotein macromolecular complexes. As the complexity of the structure of a nucleic acid increases, so does the probability of highly specific metal binding because of the greater opportunity for formation of unique ligand environments. In general, different metal ions bind to different sites in the same polynucleotide and vice versa – the same or closely located (see below) metal-binding centers of polynucleotides would bind different metal ions. For example, many specific metal-binding sites for different metal ions (for Mg<sup>2+</sup> – see Figure 6) have been found within the tRNA<sup>Phe</sup> molecule.<sup>51,53,54</sup> (also see Section 5.5).

## 4 PROPERTIES OF METAL IONS ESSENTIAL FOR INTERACTION WITH NUCLEIC ACIDS

### 4.1 Metal-nucleic Acid Bond Formation Occurs Through Ligand-exchange Reactions

As mentioned above, metal ions and nucleic acids are equal partners in metal–nucleic acid interactions. Surprisingly, the number of potential bonds (both inner- and outer-sphere) that

**Figure 7** Types of specific bonds that can be formed by hydrated metal ion (a) as compared to guanine (b). The bond types are designated as follows: 1 – hydrogen, 2 – ions, and 3 – coordinative (donor–acceptor)<sup>166</sup>

can be formed by metal ions may even exceed this number for nucleic acid bases – as schematically shown in Figure 7 comparing  $[\text{Mg}(\text{H}_2\text{O})_6]^{2+}$  and the guanine residue.

In aqueous solutions, most metal ions ( $\text{M}^+$ ,  $\text{M}^{2+}$  and  $\text{M}^{3+}$ ) exist as aqua complexes  $[\text{M}(\text{OH}_2)_x]^{n+}$ , which tend to act as acids to form aqua-hydroxo complexes  $[\text{M}(\text{OH}_2)_{x-1}(\text{OH})]^{(n-1)+}$  (see Table 1 for  $\text{pK}_a$  values) owing to the influence of the positive charge and electron acceptor property of the metal ion that facilitates deprotonation. In buffered solutions the behavior of metal ions is affected by many factors. The acidity constants for the same metal-aqua complexes may vary with ionic strength and temperature.<sup>121</sup> While  $\text{pH} < \text{pK}_a$  (Table 1) favors aqua-complex ( $\text{M}-\text{OH}_2$ ) formation,  $\text{pH} > \text{pK}_a$  favors formation of  $\text{M}-\text{OH}$ , which is resistant to ligand substitution<sup>28</sup> and also decreases or even neutralizes the positive charge of the metal complex, resulting in precipitation of metal hydroxides.<sup>167</sup> For instance, both  $\text{Pb}(\text{OH})_2$  and  $\text{Fe}(\text{OH})_2$  begin to precipitate at pH 7.5 and are almost completely insoluble ( $\sim 10^{-5}$  M) at pH 9.0 and 9.7, respectively.<sup>168</sup> In contrast,  $\text{Mg}(\text{OH})_2$  doesn't begin to precipitate until pH 10.4.<sup>168</sup> Therefore, it is important to optimize the solution pH depending on the metal ions to be used. The formation of hydroxy forms also can result in oxidation (see Section 4.5) of metal ions as, for example,  $\text{Mn}^{2+}$  and  $\text{Co}^{2+}$  at  $\text{pH} \geq 8.5$ .<sup>169</sup>

In addition to  $\text{H}_2\text{O}$  and hydroxide anion ( $\text{OH}^-$ ), other neutral (e.g.  $\text{NH}_3$ , imidazole, and nucleobases) or negatively charged ligands (e.g.  $\text{RS}^-$ ,  $\text{Cl}^-$ ,  $\text{CH}_3\text{CO}_2^-$  or  $\text{PO}_4^{3-}$ ) can be bound simultaneously to the same metal cations. Some ligands, such as  $\text{ClO}_4^-$  and  $\text{NO}_3^-$ , have no tendency to coordinate to metal ions even in rather concentrated aqueous solutions but most others (e.g.  $\text{Cl}^-$ ,  $\text{MeCO}_2^-$ , and  $\text{PO}_4^{3-}$ ) can substitute coordinated  $\text{H}_2\text{O}$  molecule(s).<sup>170</sup> Some commonly used biological buffers (e.g. polyamines, Tris, and phosphates) also can form metal-ion complexes of varying degrees of stability.<sup>122</sup> Moreover, cationic buffer components may also compete with metal ions for electrostatic and outer-sphere metal-binding sites in nucleic acids. In aqueous, buffered solutions, coordination compounds undergo

exchange reactions, wherein inert ligands are retained while labile ones are substituted by water (aquation) or by ionic buffer constituents (see **Coordination & Organometallic Chemistry: Principles**). Beyond its dependence on the nature and concentrations of metal ions and buffer solutions, the composition of the internal coordination spheres of dissolved metal ion complexes depends on pH (see above) and temperature. High temperature accelerates exchange processes, whereas low temperature (without freezing) usually slows it down.

Inner-sphere (direct) metal-nucleic acids bonds can be both formed and dissociated as result of preexisting ligand substitution (exchange) reactions, wherein inert ligands keep their places while labile ones are substituted. Mechanistically, there are generally considered to be three main classes of ligand-substitution (replacement) reactions: dissociative (1), associative (i.e. going through a transition state involving an inner-sphere complex) (2), and interchange (exchange of ligand X and Y between inner and outer coordination spheres of the metal) (3), as illustrated by the following equations:<sup>120,170</sup>

Since coordination positions are available on square-planar complexes from above or below the plane, and the fifth ligand can be added to form an inner-sphere intermediate (activated complex), an associative mechanism is generally observed for ligand substitution of such complexes. In contrast, six-coordinate complexes can form inner-sphere, seven-coordinated intermediates only with difficulty, owing to interligand steric constraints. Therefore these complexes are generally observed to react by dissociative or interchange mechanisms. Because dissociation of  $\text{M}-\text{X}$  is generally rate limiting in the dissociative mechanism, a first-order rate law obtains for such reactions; accordingly, such reactions do not depend on the concentration of nucleic acid. In contrast,

reactions that proceed by an associative mechanism are bimolecular and do depend on nucleic acid concentration.

Ligand-substitution reactions in aqueous solutions rarely proceed directly. Instead, the leaving ligand is first replaced by H<sub>2</sub>O, which is present in aqueous solution at a concentration of ~55 M, the entering ligand then substitutes the metal-bound H<sub>2</sub>O (M–OH<sub>2</sub>) in the so-called anation reaction.<sup>120</sup> Therefore, the rate constant of forward reactions, which could be considered as the *reactivity* of aquo-metal species, will parallel the order of water substitution in the inner coordination sphere of the corresponding metal ions: Cs<sup>+</sup> > Ba<sup>2+</sup> > Hg<sup>2+</sup> > K<sup>+</sup> > Cr<sup>2+</sup> ~ Cu<sup>2+</sup> > Na<sup>+</sup> > Sr<sup>2+</sup> Li<sup>+</sup> > Ca<sup>2+</sup> > Cd<sup>2+</sup> > Mn<sup>2+</sup> ~ Zn<sup>2+</sup> > Fe<sup>2+</sup> > Co<sup>2+</sup> > Mg<sup>2+</sup> > Ni<sup>2+</sup> > Pd<sup>2+</sup> > Pt<sup>2+</sup> > Cr<sup>3+</sup>.<sup>120,170,171</sup> In most cases, the interactions between hydrated metal ions and nucleic acids are fast with  $t_{1/2}$  in the range 10<sup>−9</sup>–10<sup>−3</sup> sec.<sup>171–174</sup> However, if the limiting step of a substitution reaction is dissociation of a relatively stable bond(s), for example, AMP in the reaction with Pt–Cl<sup>175</sup> or Pt–OH,<sup>176</sup> the rate of this reaction could be quite slow ( $t_{1/2}$  up to several hours or even days).

The general factors affecting the ability of coordination compounds to participate in substitution reactions include the nature of the central metal ion, the leaving and entering ligands (e.g. size, charge, nucleophilicity, and basicity), as well as the effects of other coordinated ligands, especially those in *trans* and *cis* positions to the leaving group.<sup>66</sup> The *trans* effect of donor atoms (i.e. the tendency to facilitate substitution in the position *trans* to themselves) has proven very useful for directed synthesis of model metal–nucleic acid complexes, especially in the cases of Pt<sup>2+</sup>, Pt<sup>4+</sup>, and Pd<sup>2+</sup> complexes.

Because of the polyelectrolyte effect (Section 3.1), the rate of metal–polynucleotide reaction to form ‘coordinative-covalent’ bonds will depend on the positive charge of the metal species; accordingly, the rate can be increased significantly by introduction of additional positive charge to the reagent, for example, [(NH<sub>3</sub>)<sub>2</sub>PtCl(H<sub>2</sub>O)]<sup>+</sup> → [(NH<sub>3</sub>)<sub>2</sub>Pt(H<sub>2</sub>O)<sub>2</sub>]<sup>2+</sup>. The rates of selected metal–nucleic acid reactions are given in Table 2.

## 4.2 Thermodynamic Stability of Metal–Nucleic Acid Bonds

Consistent with the definition of ‘hard and soft’ metal ions (see *Hard & Soft Acids and Bases*) based on the nature of the stable complexes that they form with different ligand donor atoms,<sup>170,177</sup> these metal ions behave similarly toward donor atoms of nucleic acids and their derivatives (Figure 8).<sup>178</sup>

‘Hard’ monovalent cations (M<sup>+</sup>) usually interact with nucleic acid polyanions only in a diffuse ‘ion atmosphere’ manner, whereas ‘hard’ and ‘borderline’ polyvalent (M<sup>≥2+</sup>) cations can form both outer- and inner-sphere complexes. ‘Soft’ metal ions tend to form inner-sphere complexes, however. ‘Hard’ metal ions (class A) prefer O-donor ligands (usually phosphate oxygens), while ‘soft’ ones (class B) prefer N-donor atoms of the nucleic acid bases as well as S atoms

**Table 2** Kinetic parameters of selected metal–nucleic acid interactions<sup>a</sup>

<sup>a</sup> $k_f$  is the rate constant for the forward reaction and  $k_r$  for the reverse one;  $t_{1/2}$  is the half-time of the forward reaction. <sup>b</sup>The metal ion concentrations were equimolar and ranged from 10<sup>−4</sup> to 2 × 10<sup>−2</sup> M nucleic acid in 0.1 M KNO<sub>3</sub>, pH 6–7, at 15 °C. <sup>c</sup>The nucleotide and metal-ion concentrations were equimolar and ranged from 10<sup>−5</sup> to 10<sup>−4</sup> M in 0.1 M KNO<sub>3</sub>, pH 5.5–7.5, at 25 °C. <sup>d</sup>The rates of coordination complex formation were determined at 15 °C at polynucleotide concentrations of about 10<sup>−4</sup> M, [Hg<sup>2+</sup>]/[nucleotide] = 0.25, in 10 mM Na phosphate buffer, pH 5.6–7.0, containing 0.25 M NaClO<sub>4</sub>. <sup>e</sup>The rate of covalent mercuration of UTP was determined at 50 °C at a nucleotide concentration of 6 × 10<sup>−4</sup> M ([Hg<sup>2+</sup>]/[nucleotide] = 6.5) in 0.1 M Na phosphate buffer, pH 6.0, containing 0.25 M NaClO<sub>4</sub>. <sup>f</sup>The nucleotide concentration ranged from 1.2 to 2.4 mM ([Pt]/[nucleotide] ≤ 0.1) in 0.5 M NaClO<sub>4</sub>, pH 7.0, and 40 °C. <sup>g</sup>The pseudo first-order rate constant for monofunctional binding to N-7 of G in chicken erythrocyte DNA was determined at a nucleotide concentration of 0.46 M ([Pt]/[nucleotide] = 0.07) in 1 mM Na phosphate, pH 6.5, containing 3 mM NaCl at 37 °C. <sup>h</sup>Since the half-life for a second-order reaction is dependent on the concentration of the reactants, the significance of these entries is not entirely clear.

in thio derivatives of nucleic acids (see *Ammonia & N-donor Ligands*; and *S-donor Ligands*).

The first-row transition metal ions have borderline ‘hard–soft’ properties. Therefore, there is no simple rule to predict comparative complex stabilities for a given metal ion with the different donor atoms. In contrast, the stability of complexes of these metal ions with a given ligand does follow a general trend. Thus the stability constants for complexes with NTP increase with the metal ion in the order Co<sup>2+</sup> < Mn<sup>2+</sup> < Zn<sup>2+</sup> < Ni<sup>2+</sup> < Cu<sup>2+</sup>,<sup>49,178</sup> which is the usual Irving–Williams order,<sup>170</sup> except for the reversal of cobalt and manganese. The usual decrease in stability with increasing atomic number is observed for the complexes with metal ions of the alkaline earth series.<sup>21,49</sup> The stability of the

**Figure 8** Classification of metal ions according to binding preferences<sup>177</sup>

complexes of these metal ions (other than  $\text{Cu}^{2+}$ ) is largely independent of the nature of the nucleic acid base in NTPs, NDPs, and NMPs because the phosphate groups constitute the most favorable ligands.<sup>115</sup> The small differences in the stability of these complexes has been interpreted as resulting from predominant outer-sphere coordination of the phosphate oxygens to the metal ions.

The tendency to favor N- over O-donors for selected 'hard' and 'borderline' metal ions is in the order  $\text{Mg}^{2+} \ll \text{Mn}^{2+} < \text{Fe}^{2+} < \text{Zn}^{2+} < \text{Co}^{2+} < \text{Cd}^{2+} < \text{Ni}^{2+} < \text{Cu}^{2+}$ .<sup>170</sup> Some metal ions in this group preferentially form mixed ternary complexes (involving phosphate oxygens and nucleic acid base nitrogens or oxygens as ligands), which are significantly more stable than those containing only one kind of donor atom.<sup>28</sup>

The relative stabilities of the metal complexes of nucleosides are generally considered to be in the order  $\text{G} > \text{A}, \text{C} \gg \text{U}, \text{T}$ ;<sup>49</sup> however, this order does not obtain universally.<sup>21,42</sup> Thus the relative base affinities of  $\text{Hg}^{2+}$  and of  $\text{Pb}^{2+}$  appear to be  $\text{T} > \text{C} > \text{A} > \text{G}$  and  $\text{C} > \text{G} > \text{A}$ , respectively.<sup>21,49,179</sup> This difference results from the variety of sites to which metal ions can bind on the nucleic acid bases. Stability constants of the complexes between selected metal ions and nucleic acids (from nucleosides to nucleoside triphosphates) are shown in Table 3.

Metal binding to polynucleotides that exist as duplexes is weaker than to single-stranded or denatured, double-stranded nucleic acids, reflecting the added binding capabilities of unpaired nucleic acid bases. Metal–nucleic acid binding could result in formation of a single bond as well as by chelation, involving multiple bonds between a metal ion and several available, appropriately located nucleic acid ligands. In some cases, one or more of the participating ligands alone may not have a particularly high affinity for the metal ion, but they get bound anyway because of the incremental gain in free energy that can be realized following initial metal-ion binding with more favorable ligands.

Thus  $\text{Mg}^{2+}$ , which binds only to phosphate oxygen anions in DNA, has a higher affinity for duplex DNA ( $K_a = 2 \times 10^5 \text{ M}^{-1}$ ) than species such as  $\text{Mn}^{2+}$  and  $\text{Cu}^{2+}$

**Table 3** Logarithms of the stability constants of metal–nucleic acid complexes in aqueous solutions at 25 °C

( $K_a = 10^4 \text{ M}^{-1}$ ), but a lower affinity than these metal ions (which also bind to nucleic acid bases while  $\text{Mg}^{2+}$  does not) for single-stranded DNA. In addition, two classes of divalent cation binding sites in tRNA have been reported.<sup>53,185</sup> The first form complexes with stability constants between  $2 \times 10^4$  and  $5 \times 10^6 \text{ M}^{-1}$ ; the second involve weaker complexes with constants ranging from  $5 \times 10^2$  to  $10^4 \text{ M}^{-1}$ , depending upon experimental conditions. For example, there are four strong and ‘intermediate’ magnesium-binding sites in yeast tRNA<sup>Phe</sup> (see Figure 6) as well as about 20 weak ones that still have structure-specific binding sites.<sup>53,54,163,185,186</sup>

### 4.3 Kinetic Lability of Metal–Nucleic Acid Bonds

In addition to the thermodynamic stability of metal–nucleic acid complexes, the rates at which nucleic acid ligands dissociate from a metal-ion coordination sphere are as important as the thermodynamic stability of the metal–nucleic acid bond.

The relative rates of reaction of the nucleic acid bases with heavy transition metal ions at neutral pH are in the same order as the relative nucleophilicities of the bases, that is  $\text{G} > \text{A} > \text{C} \gg \text{U}$  or  $\text{T}$ .<sup>79</sup> This order parallels the relative rates of reactions for *cis*-[(NH<sub>3</sub>)<sub>2</sub>Pt(OH<sub>2</sub>)<sub>2</sub>]<sup>2+</sup> (see Figure 9), while the equilibrium constants for the same reactions are very close in magnitude.<sup>79</sup> In contrast,  $\text{H}_3\text{CHgOH}$ , which is more labile to substitution, undergoes more favorable binding with deprotonation at N-3 of thymine residues in nucleic acids.<sup>79</sup> Thus the relative facilities of individual reactions can lead to differences in initial product formation (kinetic control). Subsequent changes in the metal–nucleic acid complexes can be under kinetic or thermodynamic control.

The fact that a specific ligand is considered to be kinetically inert does not necessarily mean that the metal complex will persist in solution under ordinary conditions for an indefinite length of time. Clearly, complexes that are both thermodynamically stable and kinetically inert will tend to persist for the greatest length of time. A good example is  $\text{Pt}^{2+}$ , which forms complexes with nucleic acids containing single Pt–N bonds that are very stable thermodynamically

and kinetically inert. Investigations of  $\text{Pd}^{2+}$  complexes with nucleic acids have been very useful in establishing a thermodynamic baseline for certain  $\text{Pt}^{2+}$  complexes, which undergo ligand substitution  $10^5$  times more slowly than the corresponding  $\text{Pd}^{2+}$  complexes.<sup>170</sup> Owing to the kinetic and thermodynamic properties of platinum complexes (see *Platinum: Inorganic & Coordination Chemistry*), the unforced cleavage (dissociation) of a Pt–N bond with a nucleic acid base is not expected within a reasonable time (e.g. 100 h at 37 °C).<sup>33</sup> In comparison, the lifetime for  $\text{Mg}^{2+}$  bound to DNA is  $\approx 4$  ms at room temperature.<sup>187</sup> Indeed, the rate of ligand exchange is about  $10^3$  times slower for  $\text{Mg}^{2+}$  than for  $\text{Ca}^{2+}$ , and increases in the order  $\text{Ni}^{2+} < \text{Mg}^{2+} < \text{Co}^{2+} < \text{Fe}^{2+} < \text{Mn}^{2+} < \text{Zn}^{2+} < \text{Ca}^{2+}$ .<sup>171</sup>  $\text{Mn}^{2+}$  forms thermodynamically stronger complexes than  $\text{Mg}^{2+}$ , especially when nitrogen is a ligand or with multidentate ligands, but undergoes ligand exchange about 100 times faster than  $\text{Mg}^{2+}$ .<sup>171</sup>

Complexes of platinum group metals, which are more substitution labile than platinum, can undergo isomerization, which involves cleavage of the N–metal bond formed initially under kinetic control, and formation of a more thermodynamically stable complex. For example, [(dien)Pd]<sup>2+</sup> migrates from N-7 to N-1 in A and from N-3 to N<sup>4</sup> in C; likewise [(NH<sub>3</sub>)<sub>5</sub>Ru]<sup>2+/3+</sup> moieties migrate from N-1 to N<sup>6</sup> in A and from N-3 to N<sup>4</sup> in C.<sup>33</sup> Adenosine is of special interest, because both highly reactive donor atoms N-1 and N-7 are unprotonated at neutral pH and available for metal binding, in contrast to the situation in guanosine. In spite of the fact that N-1 of A is intrinsically 320 times more basic than N-7, the ratios of stability constants,  $[M, \text{N-1}]/[M, \text{N-7}]$ , for protons and selected metal ions have been determined as follows:  $\text{H}^+ (320) \gg [(\text{dien})\text{Pd}]^{2+} (4) > \text{Ni}^{2+} (3) \geq \text{Cu}^{2+} (2.5) > \text{Zn}^{2+} (1)$ .<sup>32</sup>

In the presence of millimolar concentrations of stronger nucleophiles such as  $\text{CN}^-$  and thiourea for  $\text{Pt}^{2+}$  complexes, or molar concentrations of  $\text{Cl}^-$  for  $\text{Hg}^+$  complexes, nucleic acid base substitution takes place. However, steric constraints can lead to surprising inertness, as demonstrated for N-3-platinated T and U.<sup>33</sup> In contrast to coordination bonds of  $\text{Hg}^{2+}$  to heterocyclic N-atoms of nucleic acid bases, the covalent bond of mercury ion to C-5 of pyrimidines (see *Mercury: Organometallic Chemistry*) is stable even in the presence of 1 M NaCl.<sup>172</sup>

### 4.4 Coordination Numbers and Geometry of Metal–Nucleic Acid Complexes

Most compounds containing metal–nucleic acid bonds are *Coordination Complexes* (see *Coordination Numbers & Geometries*),<sup>170</sup> in which a central metal cation is bound (or coordinated) to a number of donor atoms that contain electron pairs (e.g. N, O, or S). In addition to the nucleic acids, many simple or sophisticated, negatively charged or neutral ligands can be bound to the same central metal ions. Water and hydroxyl anion also act as ligands (see *Water & O-donor Ligands*). The total charge carried by

**Table 4** Stoichiometries of Pt and Pt, M complexes with nucleic acid bases<sup>33</sup>

| Number of bases per metal ion | Chemical composition                                                                                                                                                                                                                                                                                                            |

<sup>a</sup>The third nucleic acid base is stacked upon a metal-coordinated base.<sup>b</sup>The third nucleic acid base is H-bonded to a metal-coordinated nucleic acid base. <sup>c</sup>Binuclear complex.

the coordination complex, being the sum of the charges possessed by a metal cation and its ligands, depends on the mode of binding (e.g. with or without proton dissociation or substitution in a nucleotide ligand) and pH, because of the ability of coordinated ligands to undergo deprotonation. The known coordination complexes of transition metals with nucleic acid constituents far outnumber those of the A group metals such as Na<sup>+</sup>, Mg<sup>2+</sup>, or Ca<sup>2+</sup>.

Metal binding to the nucleic acid bases may formally be considered in terms of number of bases *N* bound per metal *M* ( $n = N/M$ , e.g.  $n = 4, 3, 2, 1$ , or less for Pt<sup>2+</sup>) (Table 4). While the maximum number of nucleic acid bases that can be bound by single bonds to the metal ion is given by its nominal coordination number (values 2, 4, and 6 are the most common), low *n* values in multinuclear complexes can result from the binding of more than one metal at separate donor atoms in a single nucleic acid base.

Despite the fact that metal cation binding to a neutral nucleic acid base usually reduces its overall basicity (proton affinity),<sup>33</sup> this effect is not sufficient to prevent attachment of more than one metal species per nucleic acid base in the presence of an excess of the metal species. An example is the diplatination of G (via atoms N-7 and N-1) (Table 4). The N-1 atom in purine nucleosides and nucleotides is frequently identified as a binding site in solution, in spite of the fact that it has been documented less frequently in X-ray structural studies.<sup>29</sup> In N-7-platinated guanosine, the acidity of the N-1 proton is increased from p*K*<sub>a</sub> 9.3 to p*K*<sub>a</sub> 7.8,<sup>188</sup> thus making the N-1 site more susceptible to additional metal binding at neutral pH. Pt<sup>2+</sup> behaves similarly to many other transition metals in this respect.<sup>34</sup> It is also possible that a coordinated metal may increase the basicity of a nucleic acid base through charge back-donation from the metal into the heterocyclic ring.<sup>33</sup> For example, substitution of the protons at N-1 and N-7 of G as well as N-3 of U or T by Pt<sup>2+</sup>,

having a smaller polarizing effect relative to H<sup>+</sup>, actually increases the basicity of atoms N-3 in diplatinated G and O<sup>4</sup> in monoplatinated U or T. As a consequence, an additional metal ion can be bound to these sites, leading to a large class of multinuclear complexes, for example, triplatinated G.<sup>33</sup> Formation of multinuclear complexes with the participation of exocyclic amino groups has been observed for complexes of 1-methylcytosine and H<sub>3</sub>CHg<sup>+</sup> or Pt<sup>2+/4+</sup>; the metal–N bonds are formed in a condensation reaction between a M–OH moiety and an amino proton. The increased metal affinity of singly metalated base anions was also found for some heteronuclear metal complexes, for example, for Pt<sup>2+</sup> and Ag<sup>+</sup> bound to 1-methyluracil.<sup>33</sup>

The coordination number and geometry of complexes (Table 1) is thought to be dictated by the valency (i.e. oxidation state of the central metal ion – also see Section 4.5), the number of electrons possessed by the metal to be shared with ligands, the relative sizes of metal ions and ligands, as well as symmetry considerations.<sup>120</sup> Small metal ions and large ligands favor low-coordination numbers and vice versa.

Consistent with the assumption that ligands repel one another, they tend to separate from each other spatially in a fashion that minimizes ligand–ligand repulsion, while remaining bound to the central metal ion.<sup>170</sup> Accordingly, two unidentate (i.e. having one donor atom) ligands should give rise to a linear arrangement, four to a tetrahedral arrangement, and six to an octahedral arrangement. Most metal complexes conform to these geometries, but there are also many exceptions (Table 1), which are believed to result from interligand nonrepulsive interactions and chelation geometry. In particular, the metal ions of Groups 8–11 of the periodic table often form square planar, rather than tetrahedral, complexes (Table 1). Some four-coordinate Ni<sup>2+</sup> and Cu<sup>2+</sup> complexes are tetrahedral, others are planar. In six-coordinate Cu<sup>2+</sup> complexes, four ligands are strongly bound in square-planar geometry, while two weakly coordinated ligands (with longer internuclear distances) occupy axial positions that result in overall pseudooctahedral geometry of such complexes.<sup>170</sup>

There are some correlations between coordination number of metal ions (as well as geometry of the derived complexes) and metal-binding site in nucleic acid bases. Unhindered donor atoms (e.g. N-7 of purines) can be involved in octahedral complexes, while atoms that are in sterically hindered environments (e.g. N-3 of C, which is adjacent to the bulky N<sup>4</sup>H<sub>2</sub> and O<sup>2</sup> groups, or N-1 of A, which is influenced sterically by the adjacent N<sup>6</sup>H<sub>2</sub> substituent) prefer to form complexes in which the metal ion has coordination numbers of four or two.<sup>27</sup>

Strong binding between metal ions and ligands precludes their exchange and permits the resolution of geometric isomers: *cis*, in which the relevant ligands are adjacent to each other, and *trans*, in which the ligands are opposed. The dependence of metal–nucleic acid reactions on the geometrical arrangement of ligands about the metal ion is important when the reaction results from substitution of labile

ligands with retention of inert ones.<sup>189</sup> These requirements are met in the case of the reactions of the isomers of  $[(\text{NH}_3)_2\text{PtCl}_2]$ , in which only  $\text{Cl}^-$  ions are substituted, and the bond positions available for nucleic acid base binding are  $90^\circ$  apart in the *cis* isomer and  $180^\circ$  apart in the *trans* isomer (see Figure 9). Geometrical isomers would also be formed as a result of the interaction of  $[\text{PtCl}_4]^{2-}$  (see Figure 9) with nucleic acid bases because the reactivity of a Pt–Cl bond is strongly dependent on the nature of the ligands in the *trans* position.<sup>189</sup>

#### 4.5 Oxidation State of Metal Ions in Complexes with Nucleic Acids

A metal oxidation state of a metal ion usually does not change as a result of binding to nucleic acids; however, there are some exceptions for the metals in high oxidation state (see below). Some metal ions in nonstable oxidation states can be stabilized in complexes with nucleic acids; examples include  $[\text{Cr}^{3+}\text{--ATP}]$ ,<sup>190</sup>  $[\text{Co}^{3+}\text{--tRNA}]$ ,<sup>191</sup> and  $[\text{Cu}^+\text{--DNA}]$ .<sup>192</sup> Metal ions at higher oxidation states are usually stabilized by ‘hard’ ligands, those at lower oxidation states by ‘soft’ ligands (see above and *Hard & Soft Acids and Bases*).<sup>38</sup> Following coordination to a nucleic acid, certain metal ions having more than one oxidation state could be oxidized (e.g. tRNA-bound  $\text{Co}^{2+}$  was oxidized to  $\text{Co}^{3+}$ )<sup>191</sup> or reduced (e.g. DNA-bound  $\text{Cu}^{2+}$  was reduced to  $\text{Cu}^+$ , and bound  $\text{Fe}^{3+}$  was reduced to  $\text{Fe}^{2+}$ )<sup>192</sup> under mild conditions without obvious alteration of the binding sites or integrity of the nucleic acid. However, the oxidation of  $[(\text{NH}_3)_5\text{Ru}]^{2+}$  bound to DNA via N-7 of G<sup>193</sup> as well as of  $\text{Cu}^{2+}$  and  $\text{Fe}^{2+}$  bound to DNA or RNA resulted in site-specific modification and cleavage (also see Section 7) of the bound nucleic acids, presumably by generation of reactive oxygen species.<sup>166,194–197</sup>

The oxidation state of some metal ions can be reduced as a result of binding to nucleic acids. For example, certain complexes of  $\text{Pt}^{4+}$  species attached to purine residues of DNA underwent reduction to  $\text{Pt}^{2+}$  without direct damage to the platinated DNA.<sup>43</sup> However, complexes of  $\text{Pt}^{4+}$ , which are stable in high oxidation states, can act as alkylation agents. These complexes kinetically prefer binding at the N7 atom of guanine residues. A transfer of positive charge from the metal cation to the platinated guanine residue results in the formation of abasic sites that could be determined by the site-specific cleavage of DNA via a  $\beta$ -elimination reaction.<sup>166,198</sup> Interestingly, the guanine platination and formation of the abasic sites is highly specific for single-stranded DNA and does not occur in duplexes. In contrast, the complexes of  $\text{Pt}^{2+}$ , which have substantially less electron acceptor capacity than  $\text{Pt}^{4+}$ , cannot promote the oxidative removal of guanine residues.<sup>199</sup>

Amino complexes of  $\text{Ru}^{3+}/\text{Ru}^{4+}$  act similarly to their platinum relatives,  $\text{Pt}^{2+}/\text{Pt}^{4+}$  (see *Ruthenium: Inorganic & Coordination Chemistry*). Although coordination of  $[(\text{NH}_3)_5\text{Ru}]^{3+}$  to N7 of guanine residues in DNA does not

promote efficient depurination, after disproportionation of  $\text{Ru}^{3+}$  the corresponding complex of  $\text{Ru}^{4+}$  is able to carry out this reaction.<sup>200</sup> Base-specific N7-guanine modification by tetramine- $\text{Ni}^{2+}$  complexes in the presence of  $\text{KHSO}_5$  also results in  $\text{Ni}^{3+}$ -mediated oxidative guanine alkylation and removal of the modified guanine residue.<sup>196</sup> A possible ‘template’ role for nickel ions is to bridge guanine and oxidant species. This reaction is also highly specific for single-stranded or mismatched regions in polynucleotides, and has been successfully used as a structural probe for both DNA and RNA molecules.<sup>196</sup>

Reaction between DNA/RNA and  $\text{MnO}_4^-$  or  $\text{OsO}_4^{2-}$ , where the formal metal oxidation states are  $\text{Mn}^{7+}$  and  $\text{Os}^{6+}$ , results in base-specific modification of thymidine/uridine residues. These anionic metal species can oxidize the pyrimidine C5–C6 double bond, which results in formation of *cis*-5,6-dihydroxy-5,6-dihydro-pyrimidine.<sup>96</sup> This reaction is followed by opening of the pyrimidine ring and its subsequent removal from the polynucleotide chain. Permanganate can also oxidize and remove guanine residues (but not adenine) while osmium tetroxide acts much more specifically on pyrimidine residues with the following kinetic preferences (relative rates shown in parenthesis): T (45)  $\gg$  U(4.5) > dU(2.8) > C(1.8) > dC (1).<sup>96</sup> The relatively bulky permanganate and osmium tetroxide anions are very sensitive to secondary structure and react preferentially with pyrimidines in single-stranded regions, single-base mismatches, bulges, loops, unstacked nucleobases in four-way junctions, curved  $(\text{A-T})_n$  tracts, B–Z and Z–Z junctions, H-DNA, and premelting of AT-rich sequences in supercoiled DNA.<sup>201,202</sup> This feature makes them very useful probes for detection of local distortions in DNA molecules under different conditions and upon binding of other molecules including small drugs and proteins.

## 5 METAL-BINDING MODES AND STRUCTURE OF METAL–NUCLEIC ACID COMPLEXES

### 5.1 Problems in Relating Crystal Structures and Solution Composition

Most available (and most detailed) information on the mode of metal binding to nucleic acid molecules is provided by X-ray structural studies. Until recently, diffraction-quality crystals of nucleic acids with bound metal ions were generally obtained most readily for molecules of limited size (from nucleosides to oligonucleotides).<sup>30,37,60,64,137,203</sup> Interestingly, crystallization of metal complexes with nucleotides and oligonucleotides was generally found to be more facile relative to the nucleoside complexes, which may be attributed to several factors including (1) the lower stability generally observed for nucleoside complexes, (2) the presence of the phosphate group(s) in (oligo)nucleotides, which can compensate for the charge of the metal ion and thereby facilitate crystallization of the complexes as neutral species, and (3) the greater

opportunity for hydrogen bonding between water molecules coordinated to metal ions and the phosphate oxygen anions, thereby supporting specific intra- and intermolecular contacts in the crystals.<sup>30</sup> Newly developed techniques can now provide crystallization of large RNA from ribozymes<sup>55,204,205</sup> to subunits of ribosomal RNA,<sup>206</sup> allowing the study of structures of biological metal binding inside these RNA structures.

X-ray crystallographic analyses usually provide structural information that correctly represents the actual structures of metal ion–nucleic acid complexes in the crystal; this usually represents an environment that is drastically different from normal solution conditions. Obviously, such analyses are limited to complexes that are both stable and amenable to crystallization.<sup>37</sup> In comparison, solution NMR spectroscopy data are much more generally applicable to the analysis of metal ion–nucleic acid structure,<sup>53,84,148,207</sup> but can be more easily misinterpreted owing to factors such as the distribution of metal ions among several binding sites and the intrinsically weaker nature of some of the interactions that are studied. Also, nucleic acid crystallization requires the formation of ordered and uniform intermolecular interactions between nucleic acids.<sup>208,209</sup> These intermolecular interactions may either compete or interfere with the formation of certain metal–nucleic complexes and promote the formation of unnatural metal binding centers.<sup>210</sup>

Often, more than one structure of a metal–nucleic acid complex of a given nucleic acid will exist in solution at the same time, and these complexes may well be in dynamic equilibrium.<sup>36,37</sup> When multiple complexes are present, crystals are less likely to form; there are, for example, a dearth of examples of crystalline ambidentate isomers that have been characterized structurally. In principle, some of these isomers could be isolated as discrete species and crystallized separately, but this is possible only for thermodynamically stable and kinetically inert complexes. Therefore, the definition of the mode of binding of metal species to nucleic acids is usually very difficult, since many complexes of (biological) interest lack sufficient stability to permit their study as single species. Conditions favorable to crystal growth include high concentrations of the species of interest and also of organic solvents (and, therefore, low hydration) that can facilitate crystallization. Because both the specific intermolecular contacts in the crystals and the special environment from which the crystals are produced do not ordinarily exist in solution, some atom–atom interactions determined by X-ray crystallography may not occur in dilute aqueous solution where binding to (or through) water molecules would predominate.<sup>210</sup> For example, in solid-state structures, the formation of polymeric species in which each metal ion is bound to two or more nucleotide ligands is a common phenomenon. The relevance of such structures to solution geometry is also unclear. Likewise, in the highly concentrated solutions needed for crystal formation the pH, which can dramatically affect the mode of metal-ion binding, is generally not well controlled and could also change as a

result of metal ion–nucleic acid interactions. Also, the low water activity inside the crystals of nucleic acids may promote formation of unusual direct (inner-sphere) bonds between dehydrated metal ions and nucleic acids. For example, in crystals, even monovalent ions (such as  $\text{Li}^+$ ,  $\text{Na}^+$  and  $\text{Tl}^+$ ) can exhibit direct coordination with nucleobases and ribose residues.<sup>24,211</sup> Such interactions do not normally occur in dilute solutions.<sup>37,103,212</sup>

Interestingly, specific  $\text{M}^{2+}$ –nucleic acid interactions determined in solution for the hairpin ribozyme by spectroscopic and chemical interference methods were not later found in their X-ray crystal structures.<sup>127,213</sup> Even more confusing were results of X-ray crystallography<sup>214,215</sup> and initial solution experiments,<sup>216–218</sup> which both determined up to two, presumably functionally important  $\text{Mg}^{2+}$  ions in the catalytic center of the hammerhead ribozyme. However, as demonstrated recently in biochemical experiments in solution, neither of these ribozymes require either inner- or outer-sphere interactions with particular metal ions for catalysis.<sup>56,57,219,220</sup>

All of these factors dictate that great care must be exercised in relating well-defined crystal structures to the predominant structures that exist in solution.<sup>30</sup> Moreover, it is important to remember that there is a wide range of microenvironments present *in vivo*, each of which would also be expected to affect the metal–nucleic acid interactions in a fashion (superficially) analogous to a specific solvent or the absorption of the metal ions to a particular surface.<sup>221</sup>

## 5.2 Suggested Classification of Metal–Nucleic Acid Binding

According to the number of labile ligands bound to a metal ion that can be substituted by donor atoms of the nucleic acid ligand, metal species (ions and compounds) may be classified as *mono-*, *bi-*, *tri-*, or *multifunctional* reagents, up to the maximum limited by the metal coordination number.<sup>40</sup> Monofunctional attachment of a metal reagent to a nucleic acid is often followed by multifunctional binding, *chelating*, or *cross-linking*, which may occur both *intramolecularly* and *intermolecularly*. Since, in the initial monofunctional adduct, the effective local concentrations of the resulting metal species and the next potential ligand(s) can be very high (up to a few moles per liter), the rate of subsequent reactions can be much higher than the initial reaction where an associative mechanism is involved. The acceleration does not occur if a dissociative mechanism of ligand substitution obtains or if potential donor atoms are either not sterically accessible or not situated favorably.

## 5.3 Metal Binding to Nucleic Acid Bases

### 5.3.1 Monofunctional Binding

Monofunctional metal–nucleobase bonds constitute the usual mode of metal binding to nucleotides and

polynucleotides. Most known metal-binding modes involve derivatives of nucleic acid bases in which chemically unreactive groups are attached to pyrimidine N-1 and purine N-9 atoms to mimic the N-glycosyl bond. This results in nucleic acid base models that behave in a fashion reasonably similar to that of the actual naturally occurring nucleosides, at least at the level of metal coordination to the heterocyclic bases. In contrast, metal-ion binding to free nucleic acid bases often gives products that are more complex and may bear less relevance biochemically. Despite obvious limitations, work with nucleic acid base models is meaningful in that fundamental questions such as binding patterns and ligand rotation processes may be studied conveniently.<sup>25,42,48</sup>

'Pure' monofunctional, inner-sphere binding to metal species usually obtains only when some chemical or structural restriction applies. Binding of this type generally results from (1) the use of monofunctional metal reagents having only one labile ligand, for example, [(dien)PtCl]<sup>2+</sup>, [(NH<sub>3</sub>)<sub>5</sub>RuCl]<sup>2+</sup>, and H<sub>3</sub>CHgOH;<sup>26</sup> (2) transformations carried out at low pH, where additional metal-binding sites are 'blocked' via protonation;<sup>32</sup> or (3) modification of highly reactive S atoms in thio-substituted nucleic acid bases, for example, 6-thio-G and 4-thio-U.<sup>79</sup>

The mercury complexes of neutral uracil and dihydrouracil, the latter being a minor base found in tRNAs, reveal an unusual mode of coordination, wherein Hg<sup>2+</sup> is bound not to the endocyclic N-3, which is blocked by a proton, but rather to the exocyclic atom O<sup>4</sup>, which is a stronger donor atom than O<sup>2</sup>.<sup>222,223</sup> The 'usual' binding to N-3 of deprotonated U and T residues proceeds slowly in buffered solution at neutral or slightly alkaline pH with heavy metals (e.g. in reactions with H<sub>3</sub>CHgOH, Hg<sup>2+</sup>, or Pt<sup>2+</sup> species).<sup>223</sup> Although both purine and pyrimidine bases can form coordination bonds with mercury ion, U and C alone can form covalent bonds between C-5 and Hg.<sup>172</sup>

The rare nucleic acid base tautomers, ordinarily present to the extent of ~0.01% relative to the preferred tautomers, can be stabilized by metals via coordination of lone-pair electrons. For example, the 4-imino-2-oxo tautomer of cytosine has Pt<sup>4+</sup> bound to its N<sup>4</sup> group, while the 4-hydroxy-2-oxo tautomer of U and T bases is platinated at N-3.<sup>33</sup>

### 5.3.2 Bifunctional Binding

The study of intrabase chelation can be effected most readily using model compounds that lack additional binding sites. Such intrabase chelates are usually obscured by the formation of 'macrochelates' in nucleotides and polynucleotides involving phosphates or neighboring nucleic acid bases. Such intrabase chelates may, nonetheless, sometimes be of importance biochemically.

Direct (inner-sphere) chelates involving donor atoms of the nucleic acid base heterocycles have only been observed for complexes of [bis(cyclopentadienyl)Ti<sup>3+</sup>] with derivatives of guanine (involving atoms N-7 and O<sup>6</sup>), xanthine (N-1, O<sup>2</sup>),

and theophylline (N-7 and O<sup>6</sup>), as well as for a complex of Pt<sup>4+</sup> and 1-methylcytosine (N-3 and N<sup>4</sup>).<sup>33</sup> In these chelates the angles about the metals can deviate strongly from the normal 90°, which implies considerable variation of the geometry of metal-centered chelate rings. For both Cu<sup>2+</sup> and Hg<sup>2+</sup> there is also evidence of binding to cytosine via a strong bond to N-3 and a weaker one to the O<sup>2</sup> carbonyl oxygen.<sup>25</sup>

As demonstrated for the 1-methylcytosine chelate, nucleic acid base deprotonation can be achieved intramolecularly under mild conditions by a Pt–OH group already coordinated via N-3. Similar reactions might be anticipated for a large series of metal–nucleic acid base complexes, including chelates of adenine (N-1 and N<sup>6</sup>) and guanine (N-1 and N<sup>2</sup> or N-1 and O<sup>6</sup>).<sup>33</sup> However, the existence of a (N-7 and O<sup>6</sup>) chelate of guanine and *cis*-[(NH<sub>3</sub>)<sub>2</sub>Pt]<sup>2+</sup>, whose possible role as a key DNA adduct in the mechanism of antitumor action of *cis*-diclorodiammineplatinum has been controversial for some time and has not yet been proven unequivocally (*see Platinum-based Anticancer Drugs*).<sup>33,47</sup> In contrast, there are reliable data that 6-mercaptapurines bind soft metal ions such as Pd<sup>2+</sup> and Cu<sup>2+</sup> via both N-7 and S<sup>6</sup> atoms.<sup>25</sup>

## 5.4 Metal Binding to Nucleosides, Nucleotides, and Polynucleotides

### 5.4.1 Metal–Ribose Binding
